The examiner should not compress the suprapatellar pouch too firmly or push the tissues distally because the patella or normal soft tissue, including the fat pads, fills the palpated space and could be misinterpreted as synovitis or joint swelling. With a large effusion, the patella can be balloted by pushing it posteriorly against the femur with the right forefinger, while maintaining suprapatellar compression with the left hand.

At the other extreme, effusions of 4 to 8 mL can be detected by eliciting the bulge sign. This test is performed with the patient's knee extended and relaxed. The examiner strokes or compresses the medial aspect of the knee proximally and laterally with the palm of a hand to move fluid from the area. The lateral aspect of the knee is tapped or stroked, and a fluid wave or bulge appears medially (Figure 40-10). A so-called *spontaneous bulge sign* occurs if, on compression along the medial side of the joint space, fluid reaccumulates with no pressure or compression along the lateral side of the joint.

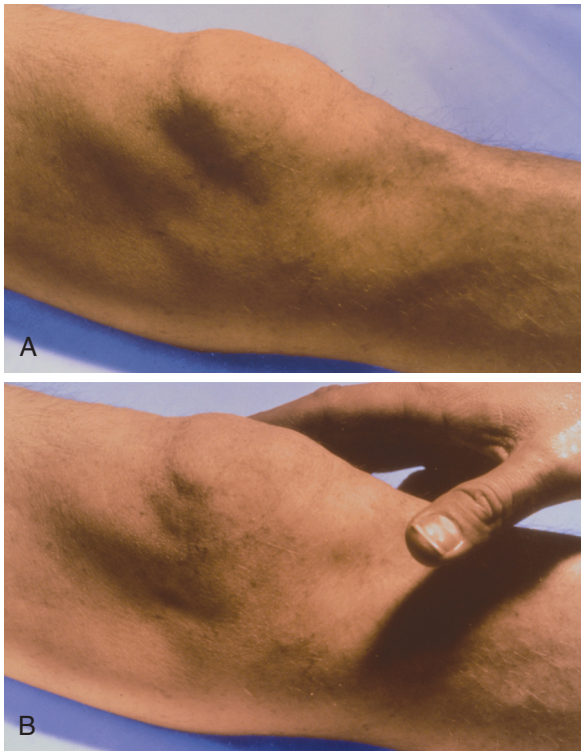

**Figure 40-10** Demonstration of the bulge sign for a small synovial knee effusion. The medial aspect of the knee has been stroked to move the synovial fluid from this area *(shaded depressed area in **A**)*. **B** shows a bulge in the previously depressed area after the lateral aspect of the knee has been tapped.

The medial and lateral tibiofemoral joint margins are palpated for tenderness and bony lipping or exostosis, as can be seen in degenerative joint disease. Joint margins can be palpated easily with the hip flexed to 45 degrees, the knee flexed to 90 degrees, and the foot resting on the examining table. Tenderness localized over the medial or lateral joint margins may represent articular cartilage disease, medial or lateral meniscal abnormality, or medial or lateral collateral ligament injury. Other causes of tenderness include pathologic conditions in the underlying bony structures.

Bursitis is another cause of localized tenderness around the knee; the two most common sites are the pes anserine and the prepatellar bursae. Exquisite local tenderness usually can be elicited if bursitis is present. Mild swelling also may be appreciated. Occasionally, the prepatellar bursa can become quite swollen. It is important not to interpret this swelling mistakenly as knee joint synovitis. The two can be differentiated because the bursal margins can be outlined by palpation; other features of true joint effusion, such as the bulge sign, are absent.

Patellofemoral malalignment is another common cause of knee pain. It is more common in female patients because of the wider Q angle caused by the broader female pelvis. The Q angle is the angle formed between the quadriceps and the patellar tendon. Patients with patellofemoral disease may complain of stiffness in the knee after a period of

flexion (the moviegoer sign) or may have particular difficulty with stair climbing. Some patients may experience a sensation of catching as the patella moves over the distal femur. Patellar palpation is best performed with the knee extended and relaxed. The patella is compressed and moved so that its entire articular surface comes into contact with the underlying femur. Slight crepitation may be observed in many normally functioning knees. Pain with crepitation may suggest patellofemoral degenerative arthritis or chondromalacia patellae.

Retropatellar pain occurring with active knee flexion and extension and secondary to patellofemoral disease may be differentiated from tibiofemoral articular pain. To test this, the examiner should attempt to lift the patella away from the knee, while passively moving the knee through the range of motion. Painless motion during this maneuver indicates that the patellofemoral joint is the likely source of the pain. In addition, the "patellar grind" test is useful in patients with extensive patellofemoral abnormality. In this test, the examiner compresses the patella distally away from the femoral condyles, while instructing the patient to contract the quadriceps isometrically. Sudden patellar pain and quadriceps relaxation indicate a positive test result. This test has frequent false-positive results, however.

Patellar stability should be assessed. The Fairbanks apprehension test is done with the patient supine, the quadriceps relaxed, and the knee in 30 degrees of flexion. The examiner slowly pushes the patella laterally. A sudden contraction of the quadriceps and a distressed reaction from the patient constitute a positive apprehension test result. A patient who has had previous patellar dislocations usually has a positive apprehension test result. The patella also can be examined for subluxation while the knee is moved through a range of motion from full flexion to extension.

The plica syndrome occasionally causes symptoms that suggest patellofemoral disease. Plicae are bands of synovial tissue, most often located on the medial side of the knee. If present, a tender band-like structure may be palpated parallel to the medial border of the patella. During flexion and extension, palpable or audible snapping may be heard, and the patient may experience symptoms of catching. Many plicae are asymptomatic, however, and they are common, so they may be considered a normal variant.

The normal knee range of motion should be from full extension (0 degrees) to full flexion of 120 to 150 degrees. Some normal individuals may be able to hyperextend to 15 degrees. Loss of full extension that is generally reversible frequently occurs with a knee joint effusion, synovitis, or both. However, permanent loss of extension caused by flexion contracture is a common finding that accompanies chronic arthritis of the knee. In advanced arthritis, such as in some cases of RA, posterior subluxation of the tibia on the femur may be observed.

Testing for ligamentous and meniscal derangements are covered in Chapter 48.

Muscle strength testing includes testing flexion supplied by the hamstrings (i.e., the biceps femoris, semitendinosus, and semimembranosus) (nerve roots L5 to S3) and extension supplied by the quadriceps femoris (L2, L3, and L4). The hamstrings are best tested with the patient prone and attempting to move the knee from 90 degrees to maximal flexion. The ankle should be kept in neutral position or dorsiflexed to remove gastrocnemius action. With the leg externally rotated, the biceps femoris, which inserts on the fibula and lateral tibia, is primarily tested, whereas flexion with internal rotation tests the semitendinosus and semimembranosus muscles, which insert on the medial side of the tibia. Extension is tested with the patient sitting upright with the knee fully extended. The examiner stabilizes the thigh with downward pressure just proximal to the knee and places downward pressure at the ankle to test the knee extensors.

## Ankle

The true ankle is a hinged joint, and movement is limited to plantar flexion and dorsiflexion. It is formed by the distal ends of the tibia and fibula and the proximal aspect of the body of the talus. Inversion and eversion occur at the subtalar joint (see Chapter 49). The tibia forms the weight-bearing portion of the ankle joint, whereas the fibula articulates on the side of the tibia. The malleoli of the tibia and fibula extend downward beyond the weight-bearing part of the joint and articulate with the sides of the talus. The malleoli provide medial and lateral stability by enveloping the talus in a mortise-like fashion. The articular capsule of the ankle is lax on the anterior and posterior aspects of the joint, allowing extension and flexion, but it is tightly bound bilaterally by ligaments. The synovial membrane of the ankle on the inside of the capsule usually does not communicate with any other joints, bursae, or tendon sheaths.

The medial and lateral ligaments surrounding the ankle contribute to medial and lateral stability of the joint. The deltoid ligament, the only ligament on the medial side of the ankle, is a triangle-shaped fibrous band that resists eversion of the foot. It may be torn in eversion sprains of the ankle. The lateral ligaments of the foot consist of three distinct bands forming the posterior talofibular, the calcaneofibular, and the anterior talofibular ligaments. These ligaments may be injured in inversion sprains of the ankle.

All tendons crossing the ankle joint lie superficial to the articular capsule and are enclosed in synovial sheaths for part of their course across the ankle. On the anterior aspect of the ankle, the tendons and the synovial tendon sheaths of the tibialis anterior, extensor digitorum longus, peroneus tertius, and extensor hallucis longus muscles overlie the articular capsule and synovial membrane. On the medial side of the ankle, posterior and inferior to the medial malleolus, lie the flexor tendons and tendon sheaths of the tibialis posterior, flexor digitorum longus, and flexor hallucis longus muscles (Figure 40-11). All three of these muscles plantar flex and supinate the foot. The tendon of the flexor hallucis longus is located more posteriorly than the other flexor tendons and lies beneath the Achilles tendon for part of its course. The calcaneus tendon (Achilles tendon), the common tendon of the gastrocnemius and soleus muscles, inserts into the posterior surface of the calcaneus, where it is subject to external trauma, various inflammatory reactions, and irritations from bone spurs beneath it. On the lateral aspect of the ankle, posterior and inferior to the lateral malleolus, a synovial sheath encloses the tendons of the peroneus longus and peroneus brevis. These muscles extend the ankle (plantar flex) and evert (pronate) the foot.

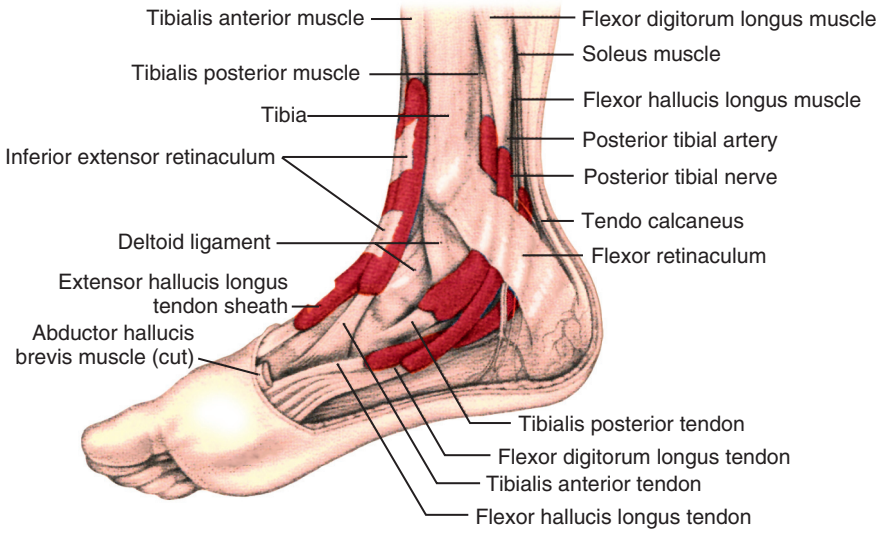

**Figure 40-11** Diagram of the ankle. Medial aspect of the ankle shows the relationship between tendons, ligaments, artery, and nerve. *(From Polley HF, Hunder GG:* Rheumatologic interviewing and physical examination of the joints, *ed 2, Philadelphia, 1978, WB Saunders. With permission from the Mayo Foundation for Medical Education and Research.)*

Each of the tendons adjacent to the ankle may be involved separately in traumatic or disease processes.

Three sets of fibrous bands or retinacula hold down the tendons that cross the ankle in their passage to the foot. The extensor retinaculum consists of a superior part (transverse crural ligament) in the anterior and inferior portions of the leg and an inferior part in the proximal portion of the dorsum of the foot. The flexor retinaculum is a thickened fibrous band on the medial side of the ankle. On the lateral side of the ankle, the peroneal retinaculum forms a superior and an inferior fibrous band. These bands bind down tendons of the peroneus longus and peroneus brevis muscles as they cross the lateral aspect of the ankle.

Synovial swelling of the ankle joint is most likely to cause fullness over the anterior or anterolateral aspect of the joint because the capsule is more lax in this area. Mild swelling of the joint may not be apparent on inspection because of the many structures crossing the joint superficially. Efforts should be made to differentiate superficial linear swelling localized to the distribution of the tendon sheaths from more diffuse fullness and swelling attributable to involvement of the ankle joint. Swelling of the heels may be observed from behind the standing patient and may be caused by enthesitis of the Achilles tendon insertion, which can occur in spondyloarthropathies (Figure 40-12).

**Figure 40-12** Achilles tendinitis in a patient with reactive arthritis. Note swelling of the left Achilles tendon insertion caused by active enthesitis and milder swelling of the right Achilles tendon insertion. *(With permission from the Mayo Foundation for Medical Education and Research, 2010.)*

It is difficult to observe synovitis of the intertarsal joints. Intertarsal joint synovitis may produce an erythematous puffiness or fullness over the dorsum of the foot.

From the normal position of rest in which there is a right angle between the leg and the foot, labeled 0 degrees, the ankle normally allows approximately 20 degrees of dorsiflexion and approximately 45 degrees of plantar flexion. Inversion and eversion of the foot occur mainly at the subtalar and other intertarsal joints. From the normal position of the foot, the subtalar joint normally permits approximately 20 degrees of eversion and 30 degrees of inversion. To test the subtalar joint, the examiner grasps the calcaneus with a hand and attempts to invert and evert it, holding the ankle motionless.

A general assessment of muscular strength of the ankle can be obtained by asking the patient to walk on toes and on heels. If the patient can walk satisfactorily on the toes and on the heels, the muscle strength of the flexors and extensors of the ankle can be considered normal. If this cannot be accomplished, it is desirable to test the muscles individually.

The principal flexors of the ankle are the gastrocnemius (nerve roots S1 and S2) and the soleus (S1 and S2) muscles. The principal extensor (dorsiflexors) of the ankle is the tibialis anterior muscle (L4, L5, and S1). The tibialis

posterior muscle (L5 and S1) is the principal inverter. To test the tibialis posterior muscle, the foot should be in plantar flexion. The examiner applies graded resistance on the medial border of the forefoot while the patient attempts to invert the foot. The principal everter of the foot are the peroneus longus (L4, L5, and S1) and peroneus brevis (L4, L5, and S1) muscles.

## Foot

CHAPTER 41

# Acute Monoarthritis

Laura McGregor • Max Field

| KEY POINTS |
| --- |
| Inflammatory arthritis causes morning stiffness and pain with restricted joint movement. |
| Pain that worsens after movement usually indicates mechanical joint pain. |
| Soft tissue disorders usually produce pain in a periarticular distribution. |
| Acute monoarthritis presentations (i.e., those that develop suddenly) are usually related to trauma. |
| Monoarthritis presentations (i.e., those that develop during a 1 to 2 day period) are usually inflammation- or infection-related. |
| Chronic monoarthritis presentation indicates pre-existing joint disease, but causes of acute monoarthritis need to be excluded. |
| Synovial fluid analysis is the most valuable laboratory test in acute monoarthritis. |

The sudden onset of monoarthritis in a synovial joint is a significant clinical event. The most serious cause is joint infection because of associated mortality (approximately 15%) and probability of impaired long-term function. However, the most common of the differential diagnoses (Table 41-1) is trauma or inflammation. Each case of monoarthritis requires immediate investigation and treatment to limit pain and prevent joint destruction. The British Society of Rheumatology and British Orthopaedic Association developed guidelines (Figure 41-1) to assist physicians in the diagnosis of the acutely swollen joint[1] based on history, examination, radiologic, and blood and synovial investigations.

Monoarthritis can also be a new presentation of more chronic forms of arthritis, and monoarticular pain can result from non-inflammatory arthropathies, periarticular problems, and bone and soft tissue disorders. These are discussed in the context of a formal differential diagnosis.

## PATIENT ASSESSMENT

### History

Physicians should inquire about the patient's age, occupation, and social, drug, travel, and sexual history. Pain and joint stiffness, its diurnal variation, and aggravating and relieving factors should be sought, and a history of swelling should be established. Specific features of relevance include trauma, joint locking, and the presence of systemic symptoms (fevers, sweats, rigors, and weight loss). Inquiring about ocular, oral, respiratory, gastrointestinal, or skin symptoms can facilitate the diagnosis if the monoarthritis is a presentation of a chronic arthropathy, related inflammatory disease, postinfectious phenomenon, or connective tissue disease. Table 41-2 summarizes symptoms and signs that characterize patients with inflammatory or non-inflammatory joint disease and soft tissue disorders[2] to help initial evaluation.

## EXAMINATION

The Regional Examination of the Musculoskeletal System (REMS) can be used to identify monoarticular abnormalities.[3] Physicians should look, feel, and move joints to assess function—comparing the affected joint and normal side, and to look for evidence of more widespread disease. In any acutely swollen joint, examination should include looking for local signs of inflammation (pain, erythema, swelling, heat, and loss of function). Any patient with pre-existing arthritis should be assessed for chronic changes to joint structure and disability. Local synovial swelling and/or effusion, joint instability, limited movement, and deformity of any single joint necessitate detailed investigation. Local monoarticular tenderness without swelling could indicate enthesitis, tendinitis, bursitis, or bone disease. A complete examination should look specifically for ocular signs, skin rashes, ulcers, and nodules.

## INVESTIGATIONS

### Blood

Inflammatory, septic, and crystal arthritides cause elevated erythrocyte sedimentation rate (ESR), C-reactive protein (CRP), and white cell count (WCC), often associated with anemia. Systemic disease involvement is assessed by renal, liver, muscle, or bone biochemical screening and protein electrophoresis. Raised uric acid levels suggest a diagnosis of gout. In acute hemarthrosis, a platelet count, international normalized ratio, and clotting studies are warranted. Blood cultures are mandatory in patients with suspected septic arthritis and should *precede* antibiotic prescription. Viral screening (IgG and IgM antibodies), antistreptolysin-O test (ASOT), and Lyme serology can be diagnostic in relevant situations.

Rheumatoid factor and anti-nuclear antibodies (ANAs) can suggest rheumatoid arthritis (RA) or systemic lupus

**TABLE 41-1** Causes of Acute Monoarticular Joint or Periarticular Pain*

*This table shows the causes of inflammation in any one joint (monoarthritis) and pain around the joint that presents without inflammation (monoarthropathy).

erythematosus (SLE), although autoantibodies can be present in infectious diseases, other autoimmune diseases, and in normal individuals. Similar limitations apply to results for anti-neutrophil cytoplasmic antibodies (ANCAs) and angiotensin-converting enzyme (ACE), so positive results should be interpreted in the clinical context. Anti-citrullinated protein antibody (ACPA) antibodies are sensitive for RA and are useful in early presentation. Other relevant blood tests include thyroid function, ferritin, vitamin D levels, and human leukocyte antigen (HLA) genes.

### Urine

The urinary tract can be a source of Gram-negative bacteria in septic arthritis in the elderly. Significant proteinuria and/or hematuria and red cell casts indicate renal damage in SLE, vasculitis, or subacute bacterial endocarditis.

### Imaging Studies

A range of imaging studies assist in diagnosis of acute monoarthritis.

- Plain radiographs identify soft tissue swelling, calcium in periarticular tissues, fractures, local bone disease, and loose bodies, as well as destructive changes in long-standing arthritides.
- Computed tomography (CT). CT scanning better identifies fractures, bone diseases, and intra-abdominal and chest pathology. It is useful when magnetic resonance imaging (MRI) is contraindicated. In acute arthritis, CT scan can show osteomyelitis in addition to acute inflammation.
- Musculoskeletal ultrasound. Ultrasound is increasingly reliable for use in rheumatology practice, as long as practitioners are appropriately trained.[4] Ultrasound is quick, efficient, inexpensive, and equally effective versus MRI and clinical examination in detecting synovitis[5] and soft tissue damage in acute shoulder injury.[6] In acute monoarthritis ultrasound can identify loculated synovial fluid for aspiration and/or injection.[7] Power Doppler views can demonstrate increased blood flow in active synovitis.[8] Ultrasound is recommended for detection of synovitis by the European League Against Rheumatism (EULAR) in early arthritis.[9]
- MRI. Although it is the best technique for soft tissue imaging, MRI is time consuming and costly. MRI can diagnose internal ligament damage and tendon enthesitis and is most effective in identifying avascular necrosis of bone. MRI is also useful when identifying the extent of inflammation in acute monoarthritis and subclinical joint involvement. EULAR also suggests MRI for diagnosis of acute early arthritis.[9]
- Arthrography. Imaging internal joint structure after injection of radiopaque solutions in association with CT scanning is useful for hip cartilage tears and in situations when MRI is not feasible.
- Radionuclide scans. Bone scanning with technetium-labeled methylene diphosphonate identifies osteoid osteomas, bone sarcomas, bony metastases, osteomyelitis, and stress fractures not seen on plain radiographs. Bone scintigraphy is helpful when excluding bone and joint disorders in patients with chronic pain syndromes. Although not specific in acute arthritides, bone scans show differences in the pattern of joint involvement between inflammatory conditions and osteoarthritis (OA). Labeled white cell scans can identify areas of infection, especially when the source of infection is uncertain in patients with septic arthritis.

## SYNOVIAL FLUID

The most useful test in acute monoarthritis is examination of synovial fluid, which should be analyzed for color and cloudiness (Table 41-3). Microscopy should be used to characterize the predominant cells, Gram stain to detect bacteria, and polarized light analysis to identify uric acid or

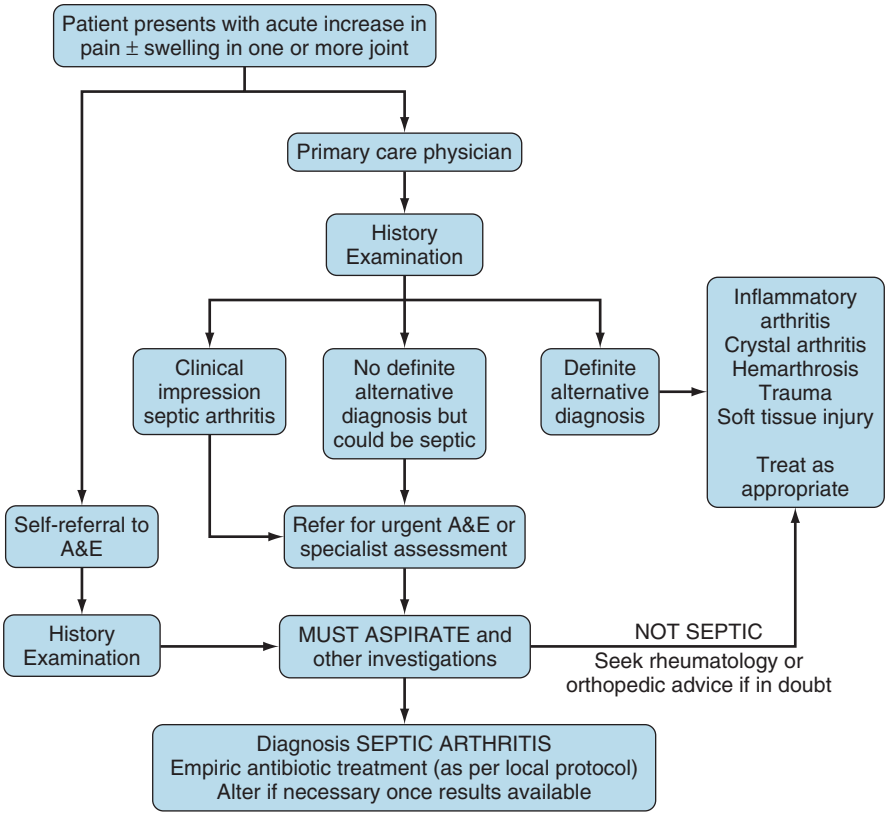

**Figure 41-1** Algorithm for assessing patients with acute monoarthritis. A&E, Accident and emergency department (or emergency room).

**TABLE 41-2** Symptoms and Signs About Which Patients Complain When They Have Inflammatory Joint Pain, Non-inflammatory Joint Pain, and Soft Tissue Problems*

| Feature | Inflammatory | Non-inflammatory | Soft Tissue Injury |
|---|---|---|---|
| **Symptoms** | | | |
| Morning stiffness | Usually >30 min | Local usually <30 min | Localized and brief |
| Constitutional symptoms | Present (fever, malaise) | None | None |
| Time of major discomfort | After prolonged inactivity | After prolonged use | During and after use |
| Locking/instability | Unlikely in acute joint disease | Suggests internal joint derangement | Unusual unless tendon damage/tear present |
| **Signs** | | | |
| Swelling | Common | Can be bone | Unusual |
| Tenderness | Diffuse over joint space | Mild over joint line | Localized periarticular |
| Inflammation | Common | Unusual | Over tendon/bursa |
| Instability | Uncommon | Occasional | Uncommon |
| Multisystem disease | More common | No | Unusual |

calcium pyrophosphate dihydrate (CPPD) crystals.[1] Identification of bacteria following synovial fluid culture can provide results even when a Gram stain is negative. *Neisseria* organisms are fastidious with low yields from culture, but PCR can detect *Neisseria*-specific DNA.

Many centers measure synovial fluid WCC, which may differentiate inflammatory and non-inflammatory presentations but crucially fails to differentiate between inflammation and infection. Low synovial fluid glucose and high lactate[10] and procalcitonin[11] are found in septic arthritis, but evidence that these can distinguish infectious from inflammatory arthritis in a clinically meaningful way is limited. Bacterial identification in synovial fluid from patients with septic arthritis can be inhibited by prior antibiotic use, and hence a careful drug history should be elicited.[12] CPPD crystals are difficult to detect, so in both cases a clinical diagnosis should not be excluded if symptoms, signs, and investigations are suggestive.

**TABLE 41-3** Synovial Fluid Characteristics in Clinical Situations, with Imaging and Investigation Techniques Best Used to Identify the Cause

| Diagnosis | Cells | Microorganisms | Appearance | Imaging Modality | Comments |
|---|---|---|---|---|---|
| Bacterial arthritis | Neutrophils, 10,000-100,000 | Gram stain usually positive | Turbid/pus | Aspiration to dryness; may need ultrasound | Systemic symptoms, Gram stain, blood and synovial fluid culture |
| Gonococcal arthritis | Neutrophils, 10,000-100,000 | Gram stain usually positive | Turbid/pus | Aspiration to dryness; may need ultrasound | Systemic symptoms, Gram stain, blood and synovial fluid culture |
| Crystal arthritis | Neutrophils, 10,000-100,000 | — | Turbid/pus | XR, CPPD | Presence of appropriate crystals<br>Acute serum urate unreliable |
| Tuberculous arthritis | Mononuclear 5000-50,000 | Acid-fast stain often negative | Turbid/pus | | At-risk population; Ziehl-Neelsen stain biopsy may be necessary |
| Inflammatory monoarthropathies | Neutrophils 5000-50,000 | — | Slightly turbid | Ultrasound/MRI for early synovitis and erosions | Serum autoantibodies such as RF, ACPA, ANA |
| Osteoarthritis | Mononuclear 0-2000 | — | Clear | XR changes | Usually non-inflammatory<br>CPPD may be present |
| Internal derangement | Red blood cells | — | Clear/turbid | MRI | Arthroscopy may be necessary |
| Trauma | Red blood cells | — | Clear/turbid | XR | Tc bone scan may aid diagnosis if radiograph normal |
| Ischemic necrosis | | — | | MRI in early disease | XR abnormal only in advanced cases |
| **Uncommon Causes**<br>Sarcoidosis | Mononuclear, 5000-20,000 | — | | CXR | |
| PVNS | Red blood cells | — | Turbid | Ultrasound and MRI | Synovial biopsy essential |
| Charcot's | Mononuclear, 0-2000 | — | | XR | CPPD may be present |
| Lyme disease | Neutrophils, 0-5000 | — | Clear/turbid | | SF eosinophilia may be found<br>Serology for *Borrelia* |
| Amyloid | Mononuclear 2000-10,000 | — | Turbid | | Synovial biopsy for Congo red stain |

ACPA, Anti-citrullinated protein antibody; ANA, anti-nuclear antibody; CPPD, calcium pyrophosphate dehydrate deposition; CXR, chest radiograph; MRI, magnetic resonance imaging; PVNS, pigmented villonodular synovitis; RF, rheumatoid factor; SF, synovial fluid; Tc, technetium; XR, radiograph.

## SYNOVIAL OR BONE BIOPSY

Arthroscopic synovial biopsy is rarely necessary, but in tuberculosis, sarcoidosis, amyloid, pigmented villonodular synovitis, lipoma arborescens, and foreign body synovitis it is often required for diagnosis.[13] Proteomic and genomic assays begin to show differences in the synovium from chronic arthritides, so synovial biopsy use may increase in the future. Bone biopsy may be needed to identify tumors and relevant factors in nonresolving osteomyelitis.

## SPECIFIC DIAGNOSES

### Acute Monoarthritis

#### Septic Arthritis (Bacterial)

The presence of bacteria in synovial fluid is a medical emergency as the mortality rate is between 7% and 15%.[14,15] Large limb joints are most frequently involved,[16] usually associated with underlying OA or inflammatory arthropathies, especially RA.[14] Patients are particularly at risk after joint surgery, including arthroplasty and intra-articular injection, as are patients with distant infections.[17] Patients with underlying disease affecting the immune response or those taking drugs that impair immune function are also at risk,[18] as are the elderly and those living in deprived socioeconomic circumstances.[14]

History often elicits an acute, painful, swollen monoarthritis, but more than 10% of patients with native joint infections are seen with polyarticular infection. An identifiable distant site of infection may be found at presentation, but fever occurs in more than 50% of cases and sweats/rigors in approximately 30%.[15] Blood cultures may identify bacteria in patients in whom synovial fluid culture is negative. When patients are first seen, ESR and CRP are almost invariably raised, but approximately 35% of all septic arthritis patients do not have a raised WCC. When infection is in the context of underlying RA, this figure rises to 50%. Impaired renal and liver function when the patient is first examined can predict a poorer outcome.[14] Plain radiographs can show soft tissue swelling, but are invariably normal at first examination. Ultrasound can localize synovitis and fluid collection to target aspiration, but MRI is required to demonstrate osteomyelitis.

Synovial fluid is usually cloudy with a high WCC, and a Gram stain should be performed.[1] High levels of synovial WCC are often noted but fail to differentiate between septic arthritis and inflammatory arthritis. Studies assessing the use of other serum and synovial fluid markers, such as procalcitonin, interleukin (IL)-6, and tumor necrosis

factor (TNF) have been performed with varying success.[19] Synovial fluid culture is mandatory but detects the organism in only approximately 50% of cases. Thus local protocols for antibiotic use should be instigated before culture results are available. Organisms detected most commonly include staphylococci (*Staphylococcus aureus* and *Staphylococcus epidermidis*), streptococci, and Gram-negative bacteria, with an increasing prevalence of methicillin-resistant *S. aureus*.[12,20] Prompt intervention can reduce mortality[10,14]; hence the joint must be aspirated to dryness, but this can usually be done without recourse to surgical intervention.[21]

Interestingly, results from history, examination, routine investigations, and outcome are identical when comparing patients with bacteria-proven septic arthritis with patients in whom a clinical diagnosis of septic arthritis is made but in whom bacteria cannot be isolated.[12] Hence normal investigations at first examination should not delay treatment in the presence of a strong clinical suspicion.

Infection with *Neisseria gonorrhoeae* should be suspected in sexually active patients who are seen with migratory arthralgias, tenosynovitis, skin rashes, and vesicles. Untreated *Neisseria* infection can also lead to destructive arthritis. Most patients will be febrile with a raised acute phase response and blood WCC, but as with other bacterial causes of septic arthritis, these may be normal at presentation.[22] Investigations should include swabs from the urethra, cervix, pharynx, and rectum, inoculated immediately on Thayer-Martin medium. In contrast with other bacterial infections, PCR has been used on synovial fluid to improve positive results.[23]

## Crystal Arthritis

See Chapters 95, Clinical Features and Treatment of Gout, and 96, Calcium Crystal Disease.

### Gout

Podagra is the classic monoarthritis of the first metatarsophalangeal joint. Other lower limb joints can be affected,[24] as can small joints of the hands, elbows, and periarticular structures.[25] Patients tend to be obese males, aged 40 to 50 years with hypertension, and consumers of excess alcohol.[26] However, post-menopausal females with low estrogen and who take loop diuretics for hypertension are also predisposed to gout. Tophi are indicative of the diagnosis.

Fever is present in 34% of patients, especially in polyarticular presentations.[27] In acute settings, blood WCC, ESR, and CRP are raised, and to this extent gout mimics septic arthritis. Serum uric acid may be raised, but levels are low in 33% during acute attacks.[28] Renal and liver function should be assessed. Negatively birefringent needle-shaped uric acid crystals are present in synovial fluid or tophi aspirates and confirm the diagnosis.[29] Synovial fluid should be examined for bacteria to exclude concomitant septic arthritis.

Routine radiographs frequently show no bony abnormalities but may identify erosions after repeated or prolonged attacks. Ultrasound and dual-energy CT (DECT) are superior imaging techniques compared with conventional radiographs.[30] A double-contour sign overlying cartilage is suggestive of gout on ultrasound. Cortical erosions, however, may be more clearly identified on MRI.[31]

### Acute Calcium Pyrophosphate Crystal Arthritis

Formally known as pseudogout, acute calcium pyrophosphate (CPP) crystal arthritis is the third commonest inflammatory arthritis.[32] It is rare in patients younger than 50 years, and the initial symptom is usually monarticular inflammation, commonest at the knees and wrists, often with concomitant OA.[32] Acute attacks often occur following a trigger such as infection, trauma, or surgery.[33] It can also occur in relation to specific diseases, such as hemochromatosis and primary hyperparathyroidism. Calcinosis of cartilage and periarticular tissues can be seen on radiographs and ultrasound, with ultrasound the more sensitive modality.[32] Synovial fluid microscopy demonstrates rhomboid-shaped crystals at ×400 magnification, and this remains the diagnostic gold standard.[34] Culture should be undertaken to exclude coexistent septic arthritis. Hemarthrosis necessitates review for an occult fracture. Repeat imaging (e.g., using MRI) may be necessary to formally exclude bone injury if clinical suspicion exists.

### Acute Calcific Periarthritis

Calcium hydroxyapatite deposition in periarticular tissues is predominately seen at the shoulder but can occur throughout the body. Underlying inflammatory arthritides, metabolic disease, and repetitive injury can be associated. Hypercalcemia necessitates that hyperparathyroidism should be excluded. Many patients are asymptomatic, although flares can be mistaken for commoner crystal arthritides.[35] Calcium crystals can be identified on routine radiographs, ultrasound, or MRI.[36]

### Calcium Phosphate Crystal Arthritis

Intra-articular deposits of basic calcium phosphate (BCP) are rare but present in older female patients with OA, with a destructive shoulder arthropathy usually on the dominant side (Milwaukee shoulder) as an acute on chronic monoarthritis.[37] The effusion is not inflammatory, but synovial fluid can be viscous and blood stained and may contain calcium aggregates and cartilage fragments. Plain radiographs show upward shoulder dislocation. CT is superior to a radiograph in identifying calcification. Even rarer clinical manifestations include tenosynovitis, peripheral nerve and spinal cord compression, and pseudotumoral deposition.[38]

### Cholesterol Crystal Arthritis

Cholesterol crystals have been reported in synovial fluid, albeit rarely, and often in association with inflammatory arthropathies. Whether these large rhomboid-shaped crystals are truly a separate cause of synovial inflammation remains a subject for speculation.

## Reactive Arthritis

Reactive arthritis characteristically presents as a large joint monoarthritis, a flitting asymmetric oligoarthritis, or

enthesitis with a history of preceding throat, urogenital, or gastrointestinal tract infection.[39] Uveitis, which may precede reactive arthritis, requires urgent review. Patients can also be seen with coexistent circinate balanitis, sterile urethritis, and keratoderma blennorrhagica. Urethral cultures should be performed. The finding of sterile inflammatory synovial fluid without crystals should exclude other acute arthritides. The acute phase response is usually high, and conventional radiologic investigations and ultrasound can identify synovial swelling and effusions. MRI is particularly useful for identifying enthesitis and extra-articular soft tissue disease.[36] Reactive arthritis is within the spondyloarthropathy spectrum, and as many as 30% of patients can have acute inflammatory back pain.[40] The high radiation exposure and insensitivity associated with standard sacroiliac joint radiographs has led to the increased use of MRI to assess for active sacroiliitis. Autoantibody tests are usually negative. The link with HLA-B27 may be suggestive but is of limited diagnostic use, although it may predict perpetuation to a chronic arthritis.[40] Antibodies against *Chlamydia*, *Shigella*, *Salmonella*, and *Campylobacter* can be found but are often negative.[41]

## LYME DISEASE

Patients with Lyme disease live in, or travel through, recognized at-risk geographic areas and are seen with expanding erythematous rashes (typically erythema migrans) after a "tick bite" resulting from *Borrelia* infection, usually *Borrelia burgdorferi*. The rash can be absent in as many as 30% of patients.[42] Large joint monoarthritis develops a few weeks after initial infection,[43] associated with a high ESR and CRP. Specific IgG antibodies, detected 4 weeks after infection, are diagnostic. Low levels of rheumatoid factor and ANAs can be detected. Synovial fluid contains polymorphs, and *Borrelia* organisms may be cultured, but PCR of synovial fluid for *Borrelia* DNA represents a superior test.[44]

### Plant Thorn Synovitis

Foreign bodies, including plant thorns, cause inflammation in intra-articular and tendon synovial tissue in hands or feet, but history of penetrating injury may be absent. Ultrasound, CT, and MRI are helpful[45] in localizing foreign bodies, but synovial biopsy can make the diagnosis. Synovial fluid can be sparse, and although usually sterile, may be infected with *Enterobacter agglomerans*,[46] a Gram-negative bacillus commonly found in soil.

#### Other Organisms That Produce Monoarthritis

Monoarthritis resulting from tuberculosis, including atypical forms that are most common,[47] should be considered in at-risk populations and people with a relevant social history. Synovial fluid contains mononuclear cells, but synovial biopsy may be required to identify organisms.

Polyarthralgia after viral infection is common. Rubella, herpes, and hepatitis B and C infections are reported to appear as monoarthritis. Arthropathies occur during infection with, and treatment for, human immunodeficiency virus. Other features in the patient's initial history and examination findings can be diagnostically useful. Arthritis, tenosynovitis, and bone lesions are reported following fungal and parasitic infections, but most infectious lesions are extensions of underlying disease. A reactive arthritis (Poncet's disease) can occur after tuberculosis infection elsewhere and may also follow viral and fungal infections.

## TRAUMA AND INTERNAL DERANGEMENT

Trauma, either acute or after repeated injury, is the most common cause of acute monoarticular pain, especially in the knee and the ankle. In the knee, torn menisci or loose bodies in the synovial fluid "wedge" between articulating surfaces and lead to sudden and painful locking and weakness when walking, which the patient describes as "giving way." Patient history is diagnostic, and an examination that uses the REMS can elicit locking by using McMurray's test. Examination for other ligament damage is mandatory, with use of tests for cruciate or collateral knee ligament stability. Careful attention to inversion and eversion stability of the ankle is also essential for monoarticular pain in that area. Plain radiographs may demonstrate abnormal architecture, dislocation, or loose bodies, but MRI is diagnostically superior and will usually establish the cause of a trauma-related diagnosis. Arthrography may be required to assess the hip for damage, particularly to establish tears in the acetabular labrum.

Stress fractures can cause monoarticular or periarticular pain on weight bearing and occur after repeated minor trauma (e.g., March metatarsal fracture) but may occur secondary to underlying local or systemic bone disease, particularly in sedentary individuals and those on prolonged bisphosphonate therapy.[48] These fractures can be missed on standard radiographs; thus CT, MRI, or bone scintigraphy are helpful in the context of persistent localizing regional articular pain.

Osteonecrosis commonly affects the hip in children (Legg-Calvé-Perthes) but can involve metatarsal heads (Freiberg), humerus, or lunate.[49] Osteonecrosis after neck or femur fracture results from impaired vascular supply and can occur in patients with connective tissues diseases, particularly when receiving high-dose glucocorticoids. Other causes of osteonecrosis include decompression sickness, hemoglobinopathies, and patients with hyperlipidemia, hyperuricemia, or high alcohol consumption. History is of monoarticular pain, and examination can be normal, but early MRI is diagnostic when plain radiographs are often normal.[50]

The presence of acute hemarthrosis suggests trauma, inherited/acquired clotting abnormalities, hemangiomas, or pigmented villonodular synovitis (PVNS). In the context of recurrent blood-stained effusions that are resistant to local interventions such as glucocorticoid injection, MRI is the investigation of choice before proceeding to synovial biopsy, which is essential for pathologic confirmation of PVNS.[50]

## POLYARTHRITIS PRESENTING AS ACUTE MONOARTHRITIS

Monoarthritis, digital dactylitis, or enthesitis may develop in patients with a personal or family history of psoriasis.[51] Radiographs may show proliferative new bone formation

along the metacarpal shaft or periarticular erosions in long-standing disease. Ultrasound and MRI can differentiate inflammation at tendon insertions from synovitis[52] and can localize synovial fluid that, if aspirated, is usually aseptic and inflammatory in character.

As many as 25% of inflammatory bowel disease patients are seen with a seronegative lower limb large joint acute monoarthritis,[53] often during exacerbation of bowel symptoms. Synovial biopsy from Crohn's disease patients may show granulomas. In cases of Whipple's disease, 60% of patients are seen with large migratory joint monoarthritis or oligoarthritis.[54] Blood tests confirm a high acute phase response with leukopenia, whereas synovial fluid usually shows a high WBC. The diagnosis is based on histologic analysis of jejunal or synovial biopsy and molecular biologic tests for *Tropheryma whippelii*.[54] There are reports of short-lived peripheral joint oligoarthritis in approximately 25% of patients with celiac disease.[55] A seronegative erosive arthritis with inflammatory synovial fluid and lymphocytic infiltrate on biopsy may occur after jejunoileal surgery for obesity,[56] but to date arthropathies are not a significant problem after less invasive gastric banding surgery.[57]

RA is reported to develop within 5 years in as many as 20% of patients who are seen at early arthritis clinics with acute knee synovitis (even for short periods as in palindromic rheumatism). Patients with a positive rheumatoid factor, ACPA, and a high acute phase response should have synovitis confirmed by MRI and/or ultrasound.[58] By achieving the American College of Rheumatology (ACR)/EULAR 2010 diagnostic criteria for RA,[59] many such patients merit earlier therapeutic intervention.

In adolescent boys, a monoarthritis may be the harbinger of spondyloarthropathy. Features of inflammatory back pain, duration of pain for more than 3 months, and presence of HLA-B27 should raise this suspicion and prompt urgent assessment for peripheral and axial inflammatory disease. Most juvenile inflammatory arthritis (JIA) patients with monoarthritis close to the 16-year age cutoff have lower limb arthritis, commonly knee or ankle involvement, and blood and radiologic investigations are similar to those with adult-onset disorders. Uveitis with inflammatory arthritis suggests the ANA-positive variety and requires regular ophthalmologic investigation. Systemic adult-onset JIA is characterized by polyarthritis, a transient salmon-pink rash, fever, and serositis. A high serum ferritin and acute phase response is found, and abnormal liver function is common. Synovial fluid shows a high neutrophil count.[60]

## MONOARTHROPATHIES ARISING FROM OTHER JOINT DISEASES

Osteoarthritis is seen as a chronic non-inflammatory polyarthropathy with a classic joint distribution. A history of intra-articular fracture or recurrent occupational-related injury (carpet fitter's knee) or previous arthrotomy can lead to a more localized OA. In younger patients with hip OA, slipped epiphysis, congenital dislocation, or avascular necrosis may antedate disease. Blood investigations will usually be normal, and provided there are no additional pathologies, synovial fluid shows a non-inflammatory level WCC.[61] Plain radiographs usually confirm the diagnosis in established disease, but ultrasound and MRI can clarify the extent of inflammation. In the presence of more inflammatory symptoms, it is important to exclude crystal deposition and/or infection,[14] but inflammatory OA may develop and require additional therapy.[61]

Neuropathic arthropathy (Charcot's joint) should be suspected in patients in whom there is a monoarthritis in the distal lower limb with severe OA on plain radiograph in association with demonstrable peripheral neuropathy. The reduced syphilis incidence means that diabetes mellitus is the commonest cause of peripheral neuropathy in the Western world.[62]

Accumulation of iron leads to hemochromatosis in synovial tissue with a secondary arthropathy. Abnormal liver function and iron saturation tests are found in association with sequence variations in the *HFE* gene, which regulates iron transport, and in more chronic cases osteophytes occur in second and third fingers. The arthropathy associated with alkaptonuria affects the spine and large joint degenerative arthritis on radiographs. Discoloration of ear cartilage and sclera is diagnostic.

## SYNOVIAL CAUSES OF NON-INFLAMMATORY MONOARTICULAR PAIN

Patients with primary or secondary tumors in periarticular tissues can be seen with single-joint pain and are usually diagnosed following routine radiographs and/or MRI.[36] Lipoma arborescens is a benign tumor, often presenting with knee swelling, in which synovium is replaced by mature fat cells. This tumor is more widely recognized with the increased use of MRI, which shows villous proliferation and characteristic features similar to subcutaneous fat.[63]

Patients with synovial osteochondromatosis are first seen with symptoms of pain and locking in the large joints, predominantly hips and knees. Synovial fluid is pale in color with few cells. Plain radiographs show calcification in synovial tissues, and synovial histology after biopsy shows the formation of osteocartilaginous bodies in the synovial membrane.[64]

Complex regional pain syndrome type I (reflex sympathetic dystrophy or algodystrophy) usually affects upper limb extremities, often following a triggering event. Pain is diffuse with a burning quality, is worsened after minor stimuli, and local weakness limits function. The affected limb is swollen and warmer than the normal side. Bone scintigraphy shows increased blood flow, and MRI patchy osteoporosis. Synovial fluid contains high protein levels but a low cell count and synovial biopsy shows hypervascularity and hyperplasia of arteriole walls with only limited cellular infiltrate or proliferation.[65]

## MONOARTICULAR ARTHRITIS IN SYSTEMIC DISEASES

Systemic vasculitides, including giant cell arteritis, ANCA-associated vasculitis, Henoch-Schönlein purpura, Behçet's disease, and connective tissue diseases, such as Sjögren's syndrome and SLE, may present with arthralgia and occasionally oligoarticular joint pain and synovitis. Relevant symptoms and signs and appropriate investigations should make the diagnosis. Sudden onset of new monoarticular

symptoms, particularly in those with SLE, when taking high-dose steroids, should raise the possibility of infection, trauma with tendon damage[66] or avascular necrosis. MRI is the investigation of choice.[67]

Sarcoidosis represents approximately 4% of cases in early synovitis clinics being linked with ankle arthritis, erythema nodosum, and bilateral hilar lymphadenopathy.[68] Patients are seronegative for rheumatoid factor and have a high acute phase response, but reported hypercalcemia is not common at presentation. ACE levels may be raised in patients with active widespread sarcoidosis but are often negative in acute joint disease.[69] Synovial fluid contains lymphocytes, and biopsy shows noncaseating granulomas.[70] Chronic arthritis is uncommon, but bone sarcoidosis may present as dactylitis with plain radiographs showing bone cysts in the phalanges.[36]

Many different fibrillar proteins located in the synovium can be associated with joint pain. Amyloid deposition is diagnosed by green birefringence after staining with Congo red on organ biopsy.[71] Amyloidosis can be primary (AL) with deposition of light chains in patients with myeloma or secondary (AA) amyloid, often associated with chronic infectious or inflammatory diseases or, rarely, of familial etiology. More than 40% of AL patients are reported to have joint related symptoms that include arthropathy, including some with synovial amyloid deposition.[72]

In hereditary periodic fever syndromes, patients, often with a Mediterranean connection, may have acute short-lived episodes of monoarthritis with serositis and high fevers. The acute phase response is high, as might be expected from the neutrophil synovial infiltrate. *HFE* gene associations now exist across a range of these disorders.[73]

Relapsing polychondritis is an episodic disorder in middle-aged Caucasians that destroys synovial joint cartilage and mimics acute monoarthritis. Ear pinna, nose, larynx, bronchi, and sclera can be affected, as can the aortic valves and aortic root. Synovial fluid is non-inflammatory, but the acute phase response is raised, often with a leukocytosis. Biopsy shows an active cellular infiltrate into cartilage, and antibodies can be detected against a variety of cartilage constituents. Repeated episodes lead to local damage and deformity.[74]

## REGIONAL DIFFERENTIAL DIAGNOSIS OF MUSCULOSKELETAL PAIN

Injuries to soft tissues can present with pain close to local joints and are often misconstrued as "arthritis." Table 41-4 shows a list of the most frequent causes of soft tissue injury. These conditions are not usually associated with active joint synovitis. Blood investigations are virtually always normal, as are plain radiographs unless there is local soft tissue swelling, calcification, or underlying joint damage. Ultrasound is the quickest method of imaging to demonstrate local injury to tendons, entheses, or bursae.[75] MRI is also reliable but costly to perform.[36]

## MONOARTICULAR PAIN RESULTING FROM PERIARTICULAR DISORDERS

Local skin infections, especially over superficial joints, can mimic the pain of acute synovitis. Deep intra-abdominal infections can cause pressure on femoral and sciatic nerves presenting with hip, knee, or sacroiliac joint pain.[76] The limited signs can lead to delay in diagnosis, with consequent increasing systemic toxicity. Investigations will be similar to those of septic arthritis, but ultrasound, CT scanning, MRI, and nuclear medicine scans, now including PET,[77] can localize unusual sites of infection. Neuropathic pain can mimic that from acute arthropathies. Pain from carpal tunnel syndrome can radiate down the arm to the fingers but equally can produce symptoms in the upper arm. Ultrasound and MRI can be used to identify pressure on the median nerve, but nerve conduction studies are the investigation of choice before injection or surgery are performed. Pressure on the lumbar (and cervical) nerve roots can cause pain that radiates into the affected limb and can localize into single joints. MRI of the spine is the investigation of choice to examine for disc protrusion or other local pathology. Blood investigations are usually normal.

Patients with chronic pain syndromes have poorly localized widespread pain often with headaches, irritable bowel syndrome, fatigue, and multiple pressure point tenderness. Symptoms can start from localized pain in a single area, which may be close to joints and hence mimic monoarthritis. Multiple trigger points are found on examination, but serum, radiologic investigations, including MRI, bone scintigraphy, and ultrasound, are normal.

**TABLE 41-4** Common Soft Tissue Disorders That Arise after Local Injury by Region

| |
|---|
| **Upper Limb** |
| Shoulder Region |
| Rotator cuff tendinitis |
| Rotator cuff tears |
| Subacromial bursitis |
| Frozen shoulder |
| Acromioclavicular pain |
| Referred pain |
| Elbow |
| Medial and lateral epicondylitis |
| Olecranon bursitis |
| Wrist and Hand |
| De Quervain's tenosynovitis |
| Trigger finger/thumb |
| **Lower Limb** |
| Hip Region |
| Iliopsoas bursitis |
| Ischiogluteal bursitis |
| Trochanteric bursitis |
| Adductor tendinitis |
| Referred pain |
| Knee |
| Prepatellar bursitis |
| Patellar tendinitis |
| Anserine bursitis |
| Ankle |
| Achilles tendonitis |
| Calcaneal and retrocalcaneal bursitis |
| Foot |
| Plantar fasciitis |
| Longitudinal arch problems |
| Hallux valgus/rigidus |
| Metatarsalgia |
| Morton's neuroma |

Bone pain may present as referred monoarticular pain from an undiagnosed fracture, undiagnosed metastatic bone disease, osteoid osteoma, Paget's disease, or osteomyelitis. Acute bone pain may be indicative of osteosarcoma when associated with a limp in adolescents. Imaging investigations may require technetium bone scans or MRI if standard radiography is not helpful.

## CONCLUSION

Monoarticular pain results from infectious, inflammatory, and non-inflammatory causes. The use of acute referral clinics can bring together apposite clinical expertise, appropriate blood and synovial fluid investigations, and imaging modalities to enable efficient diagnosis of patients' problems. Consequently, more effective treatments are used earlier in disease management, and some improved outcomes for patients with inflammatory joint diseases are being seen.

CHAPTER 42

# Evaluation and Differential Diagnosis of Polyarthritis

Ronald F. van Vollenhoven

**KEY POINTS**

- The differential diagnosis of polyarthritis is extensive.
- Diagnosing polyarthritis depends on an accurate medical history, a thorough physical examination, and appropriately chosen laboratory and imaging investigations.
- Laboratory testing and imaging, when used correctly, can lead to rapid diagnosis and diagnostic certainty.
- An early (presumptive) diagnosis and appropriate management will contribute to better outcomes.

> **"For the physician, it is essential to recognize what diseases are and whence they come; which are long and which are short; which are in the process of changing into others; which are major and which are minor."**
>
> —Hippocrates

Diagnosing patients with musculoskeletal symptoms remains one of the rheumatologist's core responsibilities. Although in the general field of medicine significant advances have been made in the use of sophisticated laboratory analyses and imaging modalities, in rheumatology, making correct diagnoses remains as much an art as a science today as in the days of Hippocrates. Moreover, for patients with polyarthritis, a purposeful and expeditious diagnostic workup has gained in importance as the benefits of early intervention have been identified for some specific diagnoses, most notably rheumatoid arthritis (RA).

In this chapter I will review the current state of the art of diagnosing polyarthritis in adults (the evaluation of children with joint symptoms is covered in Chapters 106, 107, and 108), with special reference to the proper use of laboratory testing and imaging but without detracting from the central role of a detailed history and a thorough physical examination.

## DIFFERENTIAL DIAGNOSIS OF POLYARTHRITIS

The differential diagnosis of polyarthritis, which is generally defined as arthritis occurring in four or more joints, is large; however, information that is readily available at the initial presentation will in many cases narrow the diagnosis to a limited number of possibilities. Thus, when in early spring polyarthritis of recent onset is seen in a young woman and is associated with febrile symptoms and a maculopapular rash, a viral diagnosis is very likely, and parvovirus B19 infection is a good guess. In contrast, if a middle-aged man being treated with hemodialysis wakes up one night with four hot, red, and swollen joints in his feet, it does not take an expert diagnostician to suspect gout. Nonetheless, surprises do occur, and it remains important to consider the entire spectrum of possible diagnoses when first evaluating the patient. Table 42-1 lists a comprehensive differential diagnosis of polyarthritis. The most important disease categories to be considered are outlined in the next sections.

### Viral Infections

Many different viral infections can cause a transient and self-limiting polyarthritis. One may suspect that the relatively common occurrence of self-limiting polyarthritis without further explanation usually represents viral infection, even if it is not so diagnosed. Viral arthritis is usually a symmetric polyarthritis of the small joints in the hands and feet and may therefore trigger a workup for early RA. The following viral infections are important to consider in the evaluation of polyarthritis:

- Parvovirus B19, which occurs seasonally and often appears in teenagers or young adults, is sometimes is severe enough to trigger suspicions of RA. The discovery that this infection can be associated with transient positivity for rheumatoid factor (RF) led to speculation that parvovirus might be the cause of RA.[1] Later studies clearly ruled out that possibility.[2,3] The course of parvovirus arthritis is self-limiting, but treatment may be needed for several days or weeks.[4]
- Although rubella virus infection has become uncommon as a result of vaccination, it may nonetheless be encountered from time to time in young adults, and diagnosis is, of course, extremely important when pregnancy is an issue. Rubella virus infection is self-limiting and usually mild.[5]
- Hepatitis virus infection: Each of the hepatitis viruses can cause polyarthritis as the first and sometimes only clinical manifestation.[6-8] The fact that RF can be positive in persons with viral hepatitis may lead even experienced clinicians astray.[9]
- HIV infection may cause polyarthritis, which may be the first manifestation of HIV.[10] Because early diagnosis and treatment is very important, this disease must always be considered. In contrast to most types of viral arthritis, HIV-related polyarthritis can be severe.[11]

**TABLE 42-1** The Differential Diagnosis of Polyarthritis

| Mechanism of Disease | Types of Disease |
|---|---|
| *Infections* | |
| Viral | Parvovirus B19<br>Rubella virus<br>Hepatitis A, B, C<br>Human immunodeficiency virus<br>Alphaviruses, including Chikungunya infection |
| Bacterial | Multiple infected joints in the presence of overwhelming sepsis<br>Initial phase of gonorrhea and chlamydia<br>Early phase of Lyme arthritis |
| *Diseases triggered by infection but presumed autoimmune* | |
| Reactive arthritis | After urogenital infections (*Chlamydia* and *Ureaplasma*); after gastrointestinal infections (*Yersinia, Shigella, Campylobacter,* and *Salmonella*) |
| Acute rheumatic fever | After infection with group A streptococcus |
| *Autoimmune diseases* | |
| Primary arthritides | Rheumatoid arthritis<br>Psoriatic arthritis<br>Spondyloarthropathies<br>Juvenile inflammatory arthritis |
| Transient and recurring polyarthritides | Palindromic rheumatism<br>Recurrent symmetric seronegative synovitis with pitting edema (RS3PE syndrome) |
| Systemic autoimmune disease | Systemic lupus erythematosus<br>Mixed connective tissue disease<br>Primary Sjögren's syndrome<br>Progressive systemic sclerosis and limited scleroderma<br>Behçet's disease<br>Sarcoidosis<br>Vasculitis |
| *Autoinflammatory diseases* | Adult-onset Still's disease<br>Familial Mediterranean fever and other cryopyrin-associated fever syndromes<br>Various genetic autoinflammatory conditions usually manifested first in childhood |
| *Degenerative diseases*<br>Osteoarthritis<br>Hypertrophic osteoarthropathy<br>Osteonecrosis | Includes "erosive inflammatory osteoarthritis" |
| *Metabolic diseases* | |
| Thyroid diseases | Hypothyroidism |
| Hemochromatosis | Hyperthyroidism (Graves' disease; early phase of Hashimoto's disease) |
| Hemoglobinopathies | Sickle cell anemia |
| Hemochromatosis | Thalassemiae |
| *Crystal diseases* | Gout<br>Pseudogout |
| *Deposition diseases* | Glycogen storage diseases; amyloid deposition in primary amyloidosis; mucopolysaccharidoses; light- and heavy-chain deposition diseases; others |
| *Drug-Induced diseases*<br>Generalized vasculitic drug reactions, serum sickness | |

- Alphavirus infections, including Chikungunya arthritis: In tropical countries, several alphaviruses (i.e., viruses belonging to the family of togaviruses and the class of arboviruses that are transmitted by mosquitos) are not uncommonly encountered. These infections with fanciful names such as Chikungunya[12] ("bending up" in the Akonde language), Sindbis,[13] and O'nyong-nyong[14] (meaning "severe joint pain" in the East African Acholi language) are not always self-limiting and may sometimes be destructive. Ross River virus arthritis in Australia is also caused by an alphavirus.[15] Until recently these types of viral arthritis were rarely encountered in practice outside tropical regions, but a remarkable change in the epidemiology of Chikungunya virus arthritis is taking place. As recently as 2013, this virus gained a foothold in the Caribbean region, where more than a million persons are since estimated to have been infected.[16] Frequent travel between that region and North America is now making Chikungunya infection in general, and Chikungunya arthritis more specifically, a diagnosis to be reckoned with in daily practice in the United States and Canada. Moreover, evidence indicates that the virus is adapting to mosquito strains that are ubiquitous in the United States, so the infection may become endemic in the United States as well. Chikungunya infection almost invariably causes moderate or severe myalgias and arthralgias that frequently persist weeks or months after other signs of the acute infection have subsided.[17,18]

Frank arthritis may also be seen, usually in a small joint pattern that is difficult to differentiate from seronegative RA.[19]

## Bacterial Infections

Typically, bacterial infection causes a septic monoarthritis. In rare cases, multiple joints can be seeded simultaneously, but the clinical setting will usually clarify this from the outset. Some bacterial infections behave atypically, such as gonorrhea, which can cause polyarthritis in the small joints in a relatively early phase[20]; this occurrence is believed to be due to the dissemination of immune complexes into the joints rather than to direct infection. Similarly, Lyme disease, which was initially identified as a new form of juvenile inflammatory arthritis, may cause polyarthritis in an early phase of the infection.[21] In this disease, both direct infection of the joints by *Borrelia burgdorferi* and an autoimmune reaction triggered by that organism may play a role; this possibility is discussed in more detail in Chapter 110.

Several other bacterial infections may also lead to rheumatic syndromes through mechanisms other than direct infection of the joints. A classic finding in rheumatic fever after infection with group A streptococcus is a migratory aseptic arthritis of the large joints (discussed further in Chapter 115), and various gram-negative infections of the gastrointestinal system (e.g., *Shigella* and *Campylobacter*) and genitourinary tract (e.g., *Chlamydia* and *Ureaplasma*) may trigger reactive arthritis.

## Malignancy-Associated Polyarthritis

Although direct invasion of the joint by tumor cells or metastases is very rare, polyarthritis can be a paraneoplastic phenomenon.[22] Relatively little is known about the epidemiology or pathophysiology of this entity. Diagnostic clues may be the rapid onset of a fulminant polyarthritis and associated symptoms, such as weight loss and diffuse pain; in the absence of an obvious clue, these cases can be diagnostically very challenging.[23]

## Crystal-Associated Polyarthritis

Most cases of crystal deposition disease progress from recurrent monoarticular episodes to oligoarticular and then polyarticular phases, especially when left untreated. The initial locations of the gout attack are usually the feet, ankles, and knees, but the later polyarticular manifestations may also involve the upper extremities. Thus gout in the polyarticular phase can sometimes mimic RA, and this may be particularly important to consider if patients are partially treated with nonsteroidal anti-inflammatory drugs (NSAIDs). The first presentation of gout is hardly ever polyarticular, but in pseudogout, caused by the deposition of calcium pyrophosphate dihydrate crystals, this presentation may sometimes occur. Pseudogout occurs mostly in elderly persons and affects the knees and ankles, but also the joints of the toes, and even the joints of the wrists and hands; thus it can mimic many other diseases. The deposition of hydroxyapatite crystals can give rise to an inflammation of the shoulder ("Milwaukee shoulder").

## Degenerative Arthritis

Although osteoarthritis (OA) is considered a degenerative disease by many persons, some inflammation is often detected in the affected joint. Less commonly, overt clinical inflammation is present, and the moniker "erosive-inflammatory OA," although not very well defined, is used.[24,25] The presentation in this case may be a true polyarthritis, although the experienced clinician will have little difficulty recognizing this entity, based on the distribution (predominantly the distal and proximal interphalangeal joints and frequently the first carpometacarpal joint) and typical bony hypertrophy around the affected joints.

## Metabolic Diseases

Metabolic diseases such as hemochromatosis may cause progressive degenerative and inflammatory changes in multiple joints,[26] and a polyarticular presentation may on occasion be encountered in primary amyloidosis[27] and in other deposition diseases as well.[28-30] Both hypothyroidism and hyperthyroidism may be associated with a range of musculoskeletal symptoms[31,32]; monoarticular or oligoarticular arthritis of the large joints with large effusions is most typical of hypothyroidism,[33] and muscular symptoms are most typical of hyperthyroidism,[34] but frank polyarthritis occasionally may be seen in both conditions.

## Autoimmune Diseases

Autoimmune inflammation of the joints is the most important concern for the rheumatologist when evaluating a patient with new-onset polyarthritis. In addition to diseases in which polyarthritis is the dominant manifestation, such as RA and psoriatic arthritis (PsA), consideration must be given to the spondyloarthropathies (SpAs) and to the systemic inflammatory diseases for which polyarthritis may be the first presenting manifestation, including systemic lupus erythematosus (SLE), systemic vasculitis, Sjögren's syndrome, progressive systemic sclerosis, Behçet's disease, sarcoidosis, and others.

Transient syndromes in which prominent polyarthritis is self-limiting but recurrent include palindromic rheumatism[35] and the syndrome of recurrent symmetric seronegative synovitis with peripheral edema (RS3PE syndrome).[36]

Autoinflammatory diseases with high fever, skin rashes, lymphadenopathy, and polyarthritis are more commonly diagnosed in the pediatric population but can on occasion become manifest first in adults. Important considerations in the patient with polyarthritis and fever are adult-onset Still's disease and cryopyrin-associated periodic syndromes including familial Mediterranean fever.

## Drug-Induced Arthritis and Serum Sickness

Classic descriptions of a drug-induced vasculitis or "serum sickness" include polyarthritis, which may variably be inflammatory and oligoarticular or polyarticular.[37] The clinical setting is usually sufficient to make the diagnosis, and the course is self-limiting.

## APPROACH TO THE PATIENT WITH POLYARTHRITIS

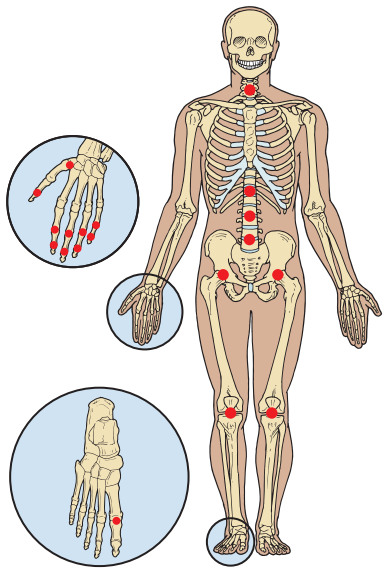
### History

Obtaining a thorough history remains a sine qua non for diagnosis, even in this age of high-tech investigations. The "seven dimensions" of the history of present illness as encountered in documentation guidelines—location, quality, quantity, duration, context, modifying factors, and associations—all provide clues to the diagnosis. The location of the symptoms makes it clear whether we are dealing with a monoarticular, oligoarticular, or polyarticular disease, but patients may sometimes focus on just one particularly bothersome joint even though additional joints are inflamed. The quality of the symptoms may provide some information; for example, pain associated with persistent morning stiffness is a notable feature of inflammation, whereas the gel phenomenon—a more short-lived stiffness when first starting to move—is typical of OA. Obviously, it is important to ascertain the severity of the symptoms. Asking the patient about the duration of symptoms, how they first started, how they fluctuate during the day, and what (s)he has done to find relief will come quite naturally. It may be less intuitive, but at least as important, to ask specifically about other symptoms, including fever and weight loss, gastrointestinal symptoms, skin rashes and mucosal lesions, ophthalmologic issues, and urogenital symptoms. The probable cause of the polyarthritis frequently becomes obvious after associated features that the patient often does not believe are important have been elicited by the clinician. Likewise, one must investigate risk factors for infectious causes of polyarthritis, such as possible exposures to infectious organisms, risk of sexually acquired infections, and recent travel to tropical countries or to areas where Lyme disease is endemic. Routinely inquiring about these types of exposures minimizes the risk of missing an important clue. Most practitioners now use a standardized form to collect this information in advance of the patient encounter.

### Physical Examination

Rheumatologists take pride in their ability to detect inflammation by simple clinical means, but they must hone this skill continuously. An inflamed joint is typically swollen, and upon palpation the swelling is soft or doughy rather than hard (as in the osteoarthritic joint). This synovial swelling may be quite obvious in some cases but is harder to establish in others. Even experienced joint assessors will not always agree where to draw the line between swollen and not swollen. In one study, six rheumatologists achieved complete agreement in only about 70% of cases,[38] and other studies have also highlighted the lack of complete agreement between experienced specialists. Fortunately, one such study also showed that specific training improves consistency.[39] Because it may not be in the patient's interest to define joints as swollen in borderline cases, I generally teach my fellows to be restrained in assessing joint swelling. One study suggested that the "squeeze test"—that is, pain on lateral compression of the metacarpophalangeal (MCP) or metatarsophalangeal joints—was more specific than other tests for arthritis, but a recent study found a low sensitivity for this test.[40,40a]

In addition to swelling ("tumor") and tenderness ("dolor"), inflamed joints may exhibit other classic signs of inflammation. Redness ("rubor") is frequently seen over joints that are affected by highly acute inflammation, such as in septic arthritis or gout, but redness is seen only rarely in RA and other autoimmune inflammations. Warmth ("calor") is more confidently assessed in larger than in smaller joints but may be a useful clue, especially in the knees, where the normal temperature gradient—with the knee being slightly cooler than the proximal musculature—may be reversed. Finally, impaired function is an almost universal finding in inflamed joints, and here it is important to distinguish between true limitations in range of motion (contractures) and limitations solely caused by pain.



The proper technique for examining joint swelling has been a matter of some discussion. The European League against Rheumatism (EULAR) has published a set of recommendations for examining the joints, along with instructional images; this handbook may serve as a good starting point for learning joint examination or for achieving standardization across different sites. Inflamed large joints often have palpable effusions, and in the knee the signs of "fluid wave" and "ballottement" can be elicited in the case of moderate or large effusions. In the initial workup of the patient with polyarthritis, a detailed examination and documentation of the individual inflamed joints, including those in the feet, will be necessary to document the range of movement (predictably decreased in the inflamed joint) or early anatomic changes. Moreover, when first evaluating a patient, a full joint examination must be performed, whereas for follow-up purposes, a more limited but standardized joint examination is recommended, the most practical one being the 28-joint count, where the MCP and proximal interphalangeal (PIP) joints of both hands, the wrist, elbows, shoulders, and knees are examined.[41] It is good practice to document such a standardized joint examination in the medical record for most visits. The more extensive 44-joint count and the even more comprehensive systematic joint count based on 68 joints are rarely used in practice for long-term follow-up of patients with arthritis.

Perhaps the two most useful pieces of information gained from the physical examination of the affected joints are the nature of the swelling (assuming swelling is present) and the pattern of joint involvement. Synovial inflammation is palpated as a soft, "doughy" swelling around the joint line, obstructing the possibility of feeling the two apposed bony edges. In contrast, hypertrophy emanating from these bony edges, such as occurs in OA, is palpated as a hard structure. Patterns of joint involvement that are easily recognized and usually point at the correct diagnosis are the symmetric involvement of wrists, MCP and PIP joints of the hands, and the corresponding joints in the feet, suggesting RA; the asymmetric involvement of predominantly the lower extremity larger joints in reactive arthritis and SpA; and involvement of multiple distal interphalangeal (DIP) joints in OA but also in some patients with PsA and prominent nail changes. The typical pattern of joint involvement in various conditions is summarized in Table 42-2. The important distinction between RA and OA is further illustrated in Figure 42-1.

**TABLE 42-2** The Typical Distribution of Joint Involvement in Some Commonly Encountered Forms of Polyarthritis

| | Rheumatoid Arthritis | Osteoarthritis | Psoriatic Arthritis | Gout/Pseudogout |
|---|---|---|---|---|
| Large weight-bearing joints | Knees and ankles, usually symmetric; hips only rarely | Hips, knees, ankles | Knees and ankles, usually asymmetric | Knees and ankles; wrists in pseudogout |
| Small joints | MCP and PIP joints in the hands; MTP joints in the feet | DIP, PIP, and first CMC joints in the hands; first MTP joint in the feet | Frequently DIP joints along with nail involvement; other small joints | Small joints of the feet; MCP joints in pseudogout |
| Spine | Cervical spine | Cervical spine and LS spine | LS spine and SI joints | No |

CMC, Carpometacarpal; DIP, distal interphalangeal; LS, lumbo-sacral; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal; SI, sacroiliac.

**Osteoarthritis**

| | |
|---|---|
| Age of onset | Most commonly occurs in individuals older than 50 years |
| Speed of onset | Slow; over years |
| Systemic symptoms | Lack of systemic symptoms |
| Joint symptoms | Joints painful without swelling or with hard, bone swelling<br>may affect joints symmetrically or asymmetrically;<br>affects small joints, large weight-bearing joints such as hips and knees, and/or the spine |
| Stiffness | Short-lived morning stiffness; "gel phenomenon";<br>stiffness when starting movement after inactivity |
| Radiologic findings | Joint-space narrowing, subchondral sclerosis, cystic changes, osteophytes |
| Lab findings | Essentially normal findings; RF, anti-CCP negative |

**Rheumatoid arthritis**

| | |
|---|---|
| Age of onset | Usual age of onset is 40-60 years<br>May begin any time in life |
| Speed of onset | May be sudden or gradual over weeks to months |
| Systemic symptoms | Frequent fatigue, low-grade fever, anorexia, muscle/joint aches, stiffness<br>Extra-articular manifestations; rheumatoid nodules, Sjögren's syndrome |
| Joint symptoms | Joints are painful, swollen and stiff;<br>affects joints symmetrically;<br>primarily affects small joints, but also affects large ones<br>Joints are swollen, warm, tender, and painful |
| Stiffness | Morning stiffness > 45 minutes;<br>may recur after rest |
| Radiologic findings | Bony erosions, soft tissue swelling, angular deformities, periarticular osteopenia, joint-space narrowing |
| Lab findings | Elevated ESR and CRP; normocytic anemia; mild leukocytosis; thrombocytosis; positive RF and/or anti-CCP |

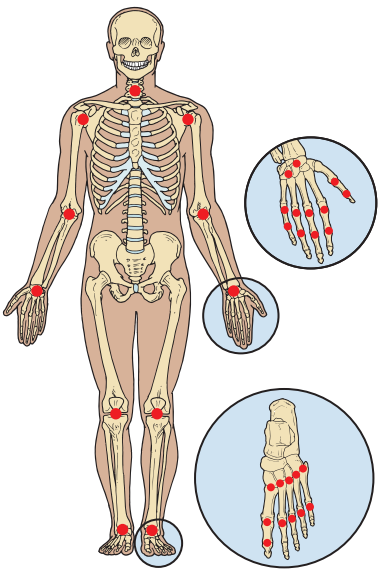


**Figure 42-1** The typical distribution of joint involvement in rheumatoid arthritis and osteoarthritis. Note that hips can be involved in late rheumatoid arthritis as well. CCP, Cyclic citrullinated peptide; CRP, C-reactive protein; DIP, distal interphalangeal; ESR, erythrocyte sedimentation rate; MCP, metacarpophalangeal; PIP, proximal interphalangeal; RF, rheumatoid factor. *(From* http://www.zoomout-ph.com/2012/02/rheumatoid-arthritis-concept-map.html*.)*

The spine must be examined even if no symptoms are reported to detect early signs of axial involvement in SpA.

Deep palpation of the large muscle groups around the shoulders and hips sometimes reveals exquisite tenderness, which, together with the patient's age of 50 years or older and a high erythrocyte sedimentation rate (ESR), might suggest a diagnosis of polymyalgia rheumatica (PMR), in which case some peripheral joint arthritis also may be present.

Furthermore, a general examination should be performed with special attention to the skin and integuments (psoriasis

and nail pitting in PsA), mucous membranes (ulcers in reactive arthritis, Behçet's disease, or SLE), lymph glands, salivary glands, thyroid, heart, lungs, eyes, and other organs based on specific suspicion.

## Laboratory Investigation

After a comprehensive history and physical examination, a laboratory workup will most likely be needed. Although some tests can be ordered "routinely," clearly many tests should be ordered on the basis of the possible differential diagnosis at this stage, at which time most often the possibilities already have been narrowed down considerably.

Inflammation can be reflected by several routine measures, including leukocytosis and neutrophilia, normocytic anemia ("of chronic disease"), and thrombocytosis. The latter in particular may be a strong indicator of systemic inflammation of significant duration and severity. The ESR is typically elevated in patients with inflammation, although it lacks specificity or sensitivity for any single diagnosis, and the same applies to the C-reactive protein (CRP). A normal ESR or CRP argues against infectious causes for the polyarthritis but does not preclude a rheumatologic diagnosis, whereas extremely high ESR or CRP values should trigger suspicion of a more serious disease underlying the polyarthritis.

Serologic testing is one of the rheumatologist's most treasured domains. The demonstration of rheumatoid factors (IgM antibodies binding to IgG; RF) in the 1940s was one of the first indications that RA was an autoimmune disease[42,43]—a concept considered inadmissible for many decades. RFs are indeed commonly seen in RA but are not more than 60% to 70% sensitive, and in the setting of an undiagnosed polyarthritis, the test must be interpreted with caution because several viral infections can cause polyarthritis with a positive RF, including parvovirus and hepatitis B and C. Moreover, RF can be positive in a wide range of rheumatologic diseases—not only RA but also Sjögren's syndrome, scleroderma, SLE, and vasculitis, for example. Nonetheless, in an early undifferentiated arthritis clinic, the presence of RF conferred a considerably increased risk of the development of persistent disease and radiologic damage.[44-47] In other words, although RF is useful in the diagnostic process, it must not be relied upon blindly; however, once the diagnosis of RA is established, the presence of RF suggests a worse prognosis.

More recently, it has become standard to test for antibodies against citrullinated proteins using an assay based on cyclic citrullinated peptides (CCPs). The test is therefore often called the anti-CCP test, but the antibodies that are detected should more properly be called anti-citrullinated protein antibodies (ACPA) because the CCP is a laboratory construct that does not exist in nature. Regardless, anti-CCP or ACPA are about equally sensitive for RA as RF but are much more specific.[48,49] Combined testing for RF and ACPA is the current standard for evaluating a patient with polyarthritis when RA is a possible diagnosis, and the specificity of the combined positivity was indeed 100% in one study,[49] although of course the sensitivity was reduced.

Other serologic tests can be useful in the evaluation of the patient with polyarthritis but must be interpreted with even greater caution. Anti-nuclear antibodies (ANAs) are positive in many autoimmune diseases, as well as in various infections, malignancies, drug-induced conditions, and so on. When ANAs are tested by immunofluorescence on human cell lines, they can be helpful in that a negative test provides a strong argument against a diagnosis of SLE, whereas a positive test will allow further testing for more specific autoantibodies (but does not prove that the patient has any particular disease). ANA by enzyme-linked immunosorbent assay (ELISA) methods may have more false-negative results. Antibodies against extractable nuclear antigens (ENAs) can point in the direction of various systemic inflammatory diseases, whereas anti-Ro/La (SS-A/SS-B) will point to Sjögren's syndrome, and anti-neutrophil cytoplasmic antibodies (ANCA) will point to systemic vasculitis.

Testing for specific infectious causes of polyarthritis can and should also be performed on the basis of clinical suspicion at this stage. Testing for hepatitis virus, HIV, and various other viruses can be considered, but it would be excessive to test for all viruses in all patients. The same can be said for serologic testing for Lyme disease or for enteric or urogenital pathogens.

### Genetic Testing

The HLA-B27 gene marker is found in approximately 3% to 8% of the population, but it is found in more than 90% of patients with ankylosing spondylitis and in 50% to 80% of patients with other SpAs. It has been argued that the HLA-B27 test is not useful because of the prevalence of this gene marker in healthy persons, but this argument does not do justice to the subtle "probabilistic" process of diagnosis; in the right clinical setting, a positive HLA-B27 test can raise the diagnostic likelihood from modest to high. Moreover, the HLA-B27 test only needs to be performed once, making it a rather cost-effective way to obtain an additional diagnostic clue.

Other genetic tests have not yet become useful in rheumatology practice. Determining whether the patient has the "shared epitope" (a constellation of HLA-DR genes that confer an elevated risk for RA) is not yet part of standard care. A genetic test exists for hereditary hemochromatosis, that is, the *HFE* gene; this test can be performed in the right clinical setting.

### Synovial Fluid Analysis

If at all possible, synovial fluid should be obtained and analyzed in the initial workup of polyarthritis. The fluid from an inflamed but aseptic joint typically is yellow and turbid and contains 5000 to 50,000 white cells/$mm^3$, mostly neutrophils. Higher leukocyte counts suggest bacterial infection but may also occur in crystal diseases, whereas lower counts would be expected in degenerative diseases. Crystal arthritis can be definitively diagnosed by demonstrating intra-cellular crystals in the joint aspirate.

## Imaging and Additional Diagnostic Procedures

Although conventional radiography is not often the key to making a diagnosis in the patient with polyarthritis, ordering plain radiographs of some of the affected joints may

nonetheless be useful. Such radiographs may reveal unexpected findings that provides diagnostic clues; in addition, radiographs may provide an indication of the severity of inflammation (juxta-articular osteopenia) and form a baseline for future evaluation, and in some cases, they may establish the diagnosis, such as when typical erosions are found and the diagnosis of RA can be made. Typical "clues" on plain radiographs are summarized in Table 42-3.

Magnetic resonance imaging (MRI) has become an important diagnostic modality in musculoskeletal diseases and has largely replaced computerized tomography, conventional tomography, and scintigraphy in this setting. MRI combines several very favorable attributes: It is noninvasive and carries minimal risk; it offers unparalleled structural detail in soft tissues; and it can be adapted to demonstrate inflammation, such as by T2 weighting, fluid-attenuated inversion recovery (FLAIR) sequencing, and the use of contrast media. The disadvantages of MRI are that it is quite time consuming for the patient and may be associated with physical and psychological discomfort (e.g., lying still in an uncomfortable position and claustrophobia); the images it provides are not as good for bone as for other tissues; only a relatively limited region can be imaged at one time; and both acquisition and pass-through costs are very high. Some of these disadvantages are lessened for low-magnetic-strength "office" MRI.[50] With use of a device that can be operated easily in a general practice setting, images of reasonable quality can be obtained and at a lower cost. However, the region that can be imaged is small, and image acquisition time is significantly longer. Based on all these considerations, when initially evaluating a patient with polyarthritis, the use of MRI will only rarely be indicated.

Use of musculoskeletal ultrasound examination (MSUS) has been increasing rapidly in the past several years. MSUS combines several attractive features: It is easily accommodated in the practice setting and even adds to the patient-physician interaction, images of good quality can be obtained and evaluated in real time based on the clinical situation, inflammation is readily detected with use of Doppler technology, and the costs are surmountable. Inflammation is easily identified using MSUS, as demonstrated in Figure 42-2. Distinct disadvantages of MSUS are that it requires an experienced physician or physician assistant to perform the procedure, it remains rather more subjective compared with MRI, and soft tissue structures can be "hidden" from view by overlying bone. Nonetheless, MSUS has increasingly become a valuable tool in rheumatology practice. Sensitivity and specificity have been shown to be similar to MRI.[51-53] Moreover, when assessing patients with polyarthritis, MSUS has proven useful to increase the diagnostic certainty on the part of the rheumatologist, both in terms of establishing that polyarthritis is truly present[54] in cases where there may be doubt and in establishing a more definitive diagnosis.[55]

Fluorescence optical imaging (FOI; "Rheumascan") is approved in Europe for evaluating arthritis in the hands. The technique is based on the intravenous injection of a fluorochrome, after which images of the hands are taken in rapid succession with a specially adapted camera. FOI has been used at some European centers, and several recent studies have demonstrated that it has similar sensitivity and

**TABLE 42-3** Clues to Diagnosis on Plain Film Radiographs

| Finding | Disease Suggested |
|---|---|
| Juxta-articular osteopenia | Early RA |
| Joint-space narrowing | RA, PsA, or OA |
| Subchondral sclerosis | OA |
| Eburnation | OA |
| Entheseal calcifications | PsA, SpA |
| Bony erosions | RA, gout |
| Osteophytes | OA |
| Chondrocalcinosis | Pseudogout |

OA, Osteoarthritis; PsA, psoriatic arthritis; RA, rheumatoid arthritis; SpA, spondyloarthropathy.

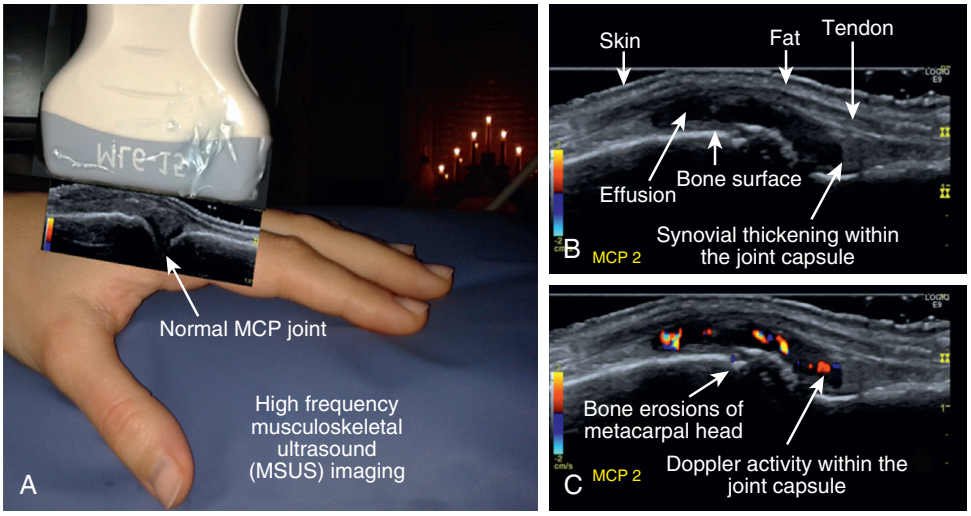

**Figure 42-2** Musculoskeletal ultrasound examination can complement the clinical examination. **A,** A normal metacarpophalangeal (MCP) joint. **B,** Synovial thickening in "gray scale" mode and an effusion. **C,** A distinct Doppler signal in the synovium, indicating inflammation. *(Original photographs courtesy Mr. Yogan Kisten, the Karolinska Institute.)*

specificity to MSUS.[56-59] However, its use is limited to the hands, and the injection can in rare instances cause allergic reactions. The device is not yet approved in the United States.

## FORMAL CRITERIA AND THEIR ROLE IN CLINICAL DIAGNOSIS

"Classification criteria" have been developed for many rheumatologic diseases, perhaps most notably for RA. These criteria were developed originally to achieve uniformity between clinicians in different health care settings, regions, or countries, and primarily so for epidemiologic or other research purposes. They were explicitly not developed as diagnostic criteria. Nonetheless, the very existence of these criteria has led to changes in the way RA and other rheumatologic diseases are perceived, and many clinicians do, in fact, rely on the classification criteria for making clinical diagnoses. The most recent classification criteria for RA, which were developed internationally under the auspices of the American College of Rheumatology (ACR) and the EULAR, were quite significantly different from previous versions[60] (Table 42-4). First, it was recognized that if a radiograph showed incontrovertible evidence for RA, then the diagnosis could be made and no other evidence was needed. Unfortunately, the criteria did not make it entirely clear exactly how certain the radiographic evidence would have to be, and most radiologists agree that there can be considerable variations in the interpretations of radiographic findings.

When radiographic evidence is lacking, the classification of RA is based on a system of points, where the number and nature of the inflamed joints, combined with several other characteristics, determines whether the patient "has" or "does not have" RA. It remains critically important to emphasize that these criteria were benchmarked on the opinions of expert clinicians and were shown to have sensitivity and specificity in the 90% range, indicating that in 1 in 10 patients, an experienced clinician will disagree with the criteria. This is not to belittle the importance of these criteria but to underscore that their use should not replace the clinical judgment of a competent specialist.

Similar considerations apply to other rheumatologic diagnoses, with the added caveat that classification criteria for diseases such as PsA,[61] ankylosing spondylitis,[62] and gout[63] usually achieve sensitivity and specificity lower than that for RA.

**TABLE 42-4** The 2010 American College of Rheumatology/European League against Rheumatism Classification Criteria for Rheumatoid Arthritis*

| Criteria | Score |
|---|---|
| Joint involvement | |
| 2-10 large joints | 1 |
| 1-3 small joints (with or without involvement of large joints) | 2 |
| 4-10 small joints (with or without involvement of large joints) | 3 |
| >10 joints (with at least 1 small joint) | 5 |
| Serology (at least 1 test result is needed for classification) | |
| Negative RF and negative ACPA | 0 |
| Low-positive RF or low-positive ACPA | 2 |
| High-positive RF or high-positive ACPA | 3 |
| Acute-phase reactants | |
| Normal CRP and normal ESR | 0 |
| Abnormal CRP or abnormal ESR | 1 |
| Duration of symptoms | |
| <6 wk | 0 |
| ≥6 wk | 1 |

*Target population (patients who can be evaluated using these criteria): those who have *at least one joint with definite clinical synovitis* (swelling), with the synovitis not better explained by another disease.

- A score of 6 or greater is needed for classification of a patient as having definite rheumatoid arthritis.
- If incontrovertible radiographic evidence of rheumatoid arthritis exists, the diagnosis can be made even if the criteria provided are not fulfilled.
- If a patient has previously fulfilled the criteria for rheumatoid arthritis, the diagnosis is maintained even if the criteria are not fulfilled on current re-examination.

ACPA, Anti-citrullinated protein antibodies; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; RF, rheumatoid factor.

## PRELIMINARY DIAGNOSES, WORKING DIAGNOSES, PRESUMPTIVE TREATMENTS, AND REASSESSMENTS: A LONGITUDINAL VIEW

Even after applying all possible diagnostic acumen and each and every available test, the diagnosis may not be entirely clear. All clinicians are familiar with the fact that medical diagnostics remains, to some extent, a probabilistic venture. Nonetheless, there comes a point where a preliminary diagnosis must be made, the patient must be informed, and a course of treatment must be chosen. This situation poses some challenges in terms of patient-physician communication. Understandably, clinicians may not want to appear uncertain when speaking with their patients, but nonetheless, it may be better to be frank and say something to the effect that "I think it is likely that you have X, but we cannot be certain. There are no further tests right now to be done, and I propose that we start treatment with Y. We will reassess in a few weeks' or months' time."

Most important, a time point for reassessment must be chosen. This point could be a few weeks or several months into the future, depending on the situation, but by explicitly marking this point, the patient will have greater acceptance if a preliminary diagnosis must be revised.

## DIFFERENTIAL DIAGNOSIS OF POLYARTHRITIS: FUTURE PERSPECTIVES

Modern rheumatologic diagnostics, applied in the setting of a clinic with experienced specialists, will achieve a final diagnosis in 60% to 90% of patients presenting with new-onset polyarthritis.[64,65] It does seem likely that further advances can be made in diagnosing specific rheumatologic disorders earlier, especially RA; the interest in this possibility is based not only on the desire to achieve an expeditious diagnosis but also on the potential for very early intervention, taking advantage of a presumed "window of opportunity" and thereby achieving better long-term results for the patient.[66] However, if this earlier diagnosis is to be achieved,

it may well have to done in the pre-clinical phase, before the patient actually has polyarthritis.

In summary, for the patient with polyarthritis, a diagnosis often can be made rapidly and confidently. Additional refinements in tools for diagnosing polyarthritis will most likely be forthcoming, and when combined with better access to medical specialty care for persons with serious musculoskeletal symptoms, excellent results will increasingly be achieved.

CHAPTER 43

# Skin and Rheumatic Diseases

Lela A. Lee • Victoria P. Werth

**KEY POINTS**

- The skin is often affected in rheumatic diseases, and many patients present with skin findings.
- Accurate diagnosis of cutaneous lesions requires knowledge of the differential diagnosis, understanding of when and when not to obtain additional studies (e.g., biopsy), and ability to interpret the results in the context of the clinical presentation.
- Skin biopsy findings of inflammatory conditions are often not definitively diagnostic.

## DIAGNOSIS OF SKIN LESIONS ASSOCIATED WITH RHEUMATIC DISEASES

The skin is a highly visible organ that is frequently affected in rheumatic diseases, and the presence of skin lesions may be helpful diagnostically. Certain caveats are worth noting before discussing the specifics. First, a major pitfall for the nondermatologist in evaluating skin lesions is incomplete knowledge of the entities in the differential diagnosis. For example, malar erythema occurs frequently in patients with systemic lupus erythematosus (SLE), but the differential diagnosis for malar erythema is rather extensive and includes conditions that are much more prevalent than lupus (e.g., rosacea), as well as conditions that are far less prevalent (e.g., Rothmund-Thomson syndrome). Patients frequently have more than one skin condition, which often makes diagnosis more challenging.

Another caveat for the nondermatologist concerns skin biopsy. The ability to determine when a skin biopsy might be diagnostically useful in many cases requires a great deal of specialized knowledge, as does the interpretation of pathology reports. It is often the case with inflammatory skin conditions that the microscopic findings are actually less diagnostically specific than the clinical examination. Unfortunately, it is common for a pathology report to list a diagnosis with no context to help the clinician understand how definitive the findings were. For example, a skin biopsy report may list psoriasis as the final diagnosis, but, depending on the specific case, the unstated additional possibilities may include nummular dermatitis, atopic dermatitis, seborrheic dermatitis, lichen simplex chronicus, dermatophytosis, or drug eruption. Particularly with regard to inflammatory skin conditions, a working knowledge of both dermatopathology and dermatology and placement of the histologic findings in the context of the clinical presentation may be necessary for the clinician to arrive at the correct diagnosis.

The above considerations notwithstanding, it is useful for the physician caring for patients with rheumatic diseases to be well versed in their cutaneous manifestations. In this chapter, we provide an overview of these manifestations, as well as a perspective on diagnosis and differential diagnosis. Therapy is discussed briefly in conditions in which treatment may be specifically directed toward the skin lesions. Etiology and pathogenesis of these diseases are covered elsewhere in this text.

## PSORIASIS

**KEY POINTS**

- The major phenotypes of psoriasis are chronic plaque, guttate, localized pustular, generalized pustular, and erythroderma. Chronic plaque and guttate are the most common phenotypes.
- Guttate psoriasis may occur a few weeks after a streptococcal infection.
- Nail changes are common but are not specific for psoriasis.
- Systemic corticosteroids should be avoided in psoriasis, if possible, because severe flaring may occur upon tapering.
- Skin findings of reactive arthritis include circinate balanitis, keratoderma blenorrhagica, oral mucosal erosions, and psoriasiform plaques.
- Skin biopsy cannot distinguish between psoriasis and reactive arthritis.

Psoriasis is one of the most common inflammatory skin diseases, affecting approximately 2% of the general population. There is a wide range of severity of skin lesions, from a few relatively asymptomatic plaques to extensive, disabling disease. The onset may be at any time during life. Once present, it may exhibit exacerbations and remissions, but it does not tend to resolve permanently. In general, onset in childhood portends more severe disease.

Skin lesions of psoriasis characteristically are sharply demarcated plaques with silvery scale and underlying erythema, although there may be a paucity of scale if the lesions have been partially treated or if they occur in

intertriginous areas. When the scale is removed, pinpoint bleeding may be observed (Auspitz sign). Lesions may occur in areas of trauma (Koebner phenomenon) such as in surgical scars. In some cases lesions contain small pustules.

General phenotypes of psoriasis are chronic plaque, guttate, localized pustular, generalized pustular, and erythroderma.[1] Chronic plaque and guttate psoriasis are the most common, and generalized pustular psoriasis and erythroderma are typically the most disabling and even life threatening. Chronic plaque psoriasis lesions are often relatively large in diameter and occur preferentially on elbows, knees, scalp, genitalia, lower back, and the gluteal cleft, although they may occur in many other locations. It is quite common for only one area of skin, such as the scalp, to be affected. Guttate lesions are relatively small in diameter and usually quite numerous, distributed preferentially on the trunk and proximal extremities (Figure 43-1). Guttate psoriasis occurs relatively commonly in children and young adults, often manifesting a few weeks after a streptococcal infection.

Nail changes are common, occurring in approximately half of patients, and are often mistaken for fungal infection. Findings include pitting, onycholysis ("oil spots"), dystrophy of nails, and loss of the nail plate. These changes are not specific for psoriasis. Notably, pitting may occur as a result of trauma. Nail changes are more frequent in patients with arthritis of the distal interphalangeal joints.[2]

**Figure 43-1** **A**, Guttate psoriasis resembles "drops" of discrete scaly papules with erythema, often on the trunk. **B,** Plaque psoriasis with thick micaceous scale on the thighs. (***A**, Courtesy Dr. Nicole Rogers, Tulane University School of Medicine, New Orleans; **B**, courtesy Dr. Abby Van Voorhees, University of Pennsylvania).*

Arthritis occurs more often in patients with severe cutaneous disease, but cutaneous disease need not be present at all. Remissions and exacerbations of arthritis do not correlate well with remissions and exacerbations of skin disease. The presence of psoriatic skin lesions may be helpful in supporting a diagnosis of psoriatic arthritis, although many patients with psoriasis have joint disease unrelated to psoriasis.

The physician usually makes the diagnosis of psoriatic skin disease on clinical grounds alone, largely on the basis of the morphology and distribution of lesions. The differential diagnosis may be extensive and includes in selected cases nummular eczema, seborrheic dermatitis, candidiasis (in intertriginous areas), pityriasis rubra pilaris, Bowen's disease or Paget's disease (for isolated plaques), drug eruption, pityriasis rosea, pityriasis lichenoides, dermatophytosis, lichen planus, secondary syphilis, parapsoriasis, cutaneous lupus (especially subacute cutaneous lupus erythematosus [SCLE]), and dermatomyositis. In cases in which the diagnosis is not clear cut, biopsy may be helpful. The histologic findings may range from virtually diagnostic for psoriasis to merely consistent with but not diagnostic. Histologically, psoriasis cannot generally be distinguished from the skin lesions seen in reactive arthritis.

Common topical therapies include corticosteroids, tar, anthralin, calcipotriene, and tazarotene.[3] Phototherapy with sunlight, narrow-band ultraviolet B (UVB), or psoralen ultraviolet A (PUVA)-range is a mainstay of therapy for many patients. Common systemic therapies include methotrexate, acitretin, and biologic agents targeting tumor necrosis factor (TNF) or interleukin (IL)-12/23. Cyclosporine may be useful to attain relatively rapid control of severe psoriasis, but it is less often used as a long-term therapy. Although topical corticosteroids are an acceptable treatment for many patients, systemic corticosteroids are avoided for the treatment of cutaneous disease, in particular because of the observation of severe flaring of psoriasis following withdrawal of systemic corticosteroids.

## REACTIVE ARTHRITIS

Circinate balanitis is the most common of the characteristic mucocutaneous lesions of reactive arthritis.[4] Small erythematous papules and pustules coalesce to form serpiginous erosive or crusted plaques on the glans penis. In uncircumcised men, the appearance is more often that of erosion rather than crust because the moisture and trauma minimize the formation of crust. In circumcised men, crusting may be more obvious than erosion.

Lesions that are initially similar to the small erythematous papules and pustules of the genital region may develop on the palms and, particularly, the soles of the patient. With time, these lesions, termed *keratoderma blenorrhagica*, tend to become markedly hyperkeratotic (Figure 43-2). They may coalesce into large plaques or generalized hyperkeratosis involving the entire plantar surface, or they may remain discrete, erythematous, hyperkeratotic papules a few millimeters in diameter.

**Figure 43-2** Reactive arthritis with keratoderma blennorrhagica of the feet.

Erythematous, scaly plaques indistinguishable from psoriasis may appear elsewhere on the skin, including the scalp, elbows, and knees. When lesions occur around the nails, it is common for there to be hyperkeratosis underneath the nails. Pitting is not typical of reactive arthritis, but thickening, ridging, or shedding of the nail plate may occur. Erosions of the oral mucosa are relatively common on the tongue, buccal mucosa, and palate.

The diagnosis of the cutaneous lesions is usually made on a clinical basis. Skin biopsy may be helpful in excluding many entities in the differential diagnosis, but in general, it cannot exclude psoriasis. Unfortunately, the major condition in the differential diagnosis of the skin lesions is usually psoriasis. One somewhat distinguishing histologic feature is that the older lesions of keratoderma blenorrhagica may have a considerably thickened stratum corneum, corresponding to the markedly hyperkeratotic papules seen grossly.

For the genital lesions, conditions to consider in the differential diagnosis may include candidiasis, psoriasis, dermatitis, Bowen's disease, Paget's disease, squamous cell carcinoma, Zoon's balanitis, erosive lichen planus, lichen sclerosus (balanitis xerotica obliterans), aphthosis, fixed drug eruption, and certain infectious diseases. The differential diagnosis for lesions on the soles and palms may include psoriasis, hereditary or acquired hyperkeratosis of the palms and soles, pustular eruption of the palms and soles, pompholyx, scabies, and dermatophytosis. The differential diagnosis for oral lesions may include geographic tongue, lichen planus, candidiasis, aphthae, and autoimmune bullous diseases.

The approach to treatment of skin lesions is similar to that for psoriasis, particularly in cases in which the lesions are persistent. Choice of topical therapies may be somewhat limited because of the sites involved. The oral mucosa is a difficult site to deliver medication topically, and the genital area may develop irritant reactions to certain topical medications. Often, topical corticosteroids are preferred for both areas because of low potential for irritation and the availability of topical preparations designed for these sites. In the genital area, suprainfection with *Candida* may occur, and concurrent therapy with a topical or systemic anticandidal medication may be necessary on occasion.

## RHEUMATOID ARTHRITIS

**KEY POINTS**

- **Skin findings associated with RA are characteristically granulomatous or neutrophilic.**
- **The major granulomatous cutaneous finding is the rheumatoid nodule. The major neutrophilic conditions are vasculitis, Sweet's syndrome, and pyoderma gangrenosum.**
- **Sweet's syndrome and pyoderma gangrenosum are part of a group of noninfectious inflammatory conditions called *neutrophilic dermatoses*. These conditions may be associated with internal diseases, including rheumatic diseases.**
- **Interstitial granulomatous dermatitis (IGD) and palisaded neutrophilic and granulomatous dermatitis (PNGD) are rare conditions that may be associated with RA or other rheumatic diseases. It is not clear whether IGD and PNGD are distinct entities or variants of the same condition.**
- **The cutaneous eruptions of juvenile idiopathic arthritis and adult-onset Still's may be similar to viral exanthems or drug eruptions, but they are distinctive in that they clear completely between episodes.**

The major skin manifestations associated with rheumatoid arthritis (RA) generally fall under granulomatous lesions, exemplified by the rheumatoid nodule, and neutrophilic lesions, exemplified by vasculitis and pyoderma gangrenosum.

Rheumatoid nodules are the most common cutaneous manifestations of RA.[5] They occur more often in seropositive patients and correlate somewhat with higher rheumatoid factor titers, more severe arthritis, and increased risk for vasculitis. Nodules are usually relatively deep, firm, and painless and tend to develop over areas of pressure and trauma, such as the extensor forearms, fingers, olecranon processes, ischial tuberosities, sacrum, knees, heels, and posterior scalp (Figure 43-3). In patients who wear glasses, nodules may develop under the bridge or nosepieces. In most cases, rheumatoid nodules are in the subcutaneous tissue and/or deep dermis, but occasionally they may occur more deeply or more superficially.

Clinically, depending on the presentation, numerous entities may be in the differential diagnosis, including infections, inflammatory disorders, and benign tumors. If needed, biopsy of a nodule may be quite helpful in establishing the diagnosis. Rheumatoid nodules exhibit a distinctive histologic finding called necrobiosis, a fibrinoid degeneration of the connective tissue, surrounded by palisaded histiocytes. Necrobiosis is also a characteristic feature of granuloma annulare and necrobiosis lipoidica diabeticorum. Although necrobiosis lipoidica diabeticorum is easily distinguished from rheumatoid nodule clinically, the subcutaneous variant of granuloma annulare may be difficult to distinguish, both clinically and histologically.

**Figure 43-3** Rheumatoid nodule over the extensor tendon of the distal interphalangeal joint.

The term *rheumatoid nodulosis* has been used to describe an entity characterized by subcutaneous rheumatoid nodules, cystic bone lesions, rheumatoid factor positivity, and arthralgias in patients with little or no evidence of systemic manifestations of RA or erosive joint disease.[6] Older males are preferentially affected.

The development of nodules in RA patients undergoing treatment with methotrexate has been noted by several observers and termed *accelerated rheumatoid nodulosis*.[7] The nodules are newly appearing and occur preferentially on the hands. There are also case reports of the phenomenon in RA patients treated with etanercept.

The other major type of cutaneous lesion associated with RA is neutrophil predominant. Rheumatoid vasculitis occurs more frequently in patients who are seropositive and have rheumatoid nodules, and it often occurs relatively late in the course of the disease.[8] Vessels of any size may be affected. In the skin, vasculitis may appear as purpuric papules and macules, nodules, ulcerations, or infarcts. Bywaters lesions are periungual or digital pulp purpuric papules that represent a small vessel vasculitis but are not necessarily associated with vasculitic lesions elsewhere.

The differential diagnosis of purpuric or petechial lesions may include stasis dermatitis, Schamberg's purpura, platelet dysfunction, petechial drug eruptions, viral exanthems, emboli, thromboses, and sludging. Of these, Schamberg's purpura, a relatively common condition unassociated with systemic disease, is probably the most frequently confused with small vessel vasculitis. Skin biopsy may be helpful in establishing the diagnosis of vasculitis, particularly if an early lesion is sampled, although rheumatoid vasculitis cannot be distinguished histologically from many other causes of small vessel vasculitis. Immunofluorescent examination of an early lesion may be helpful in ruling out immunoglobulin (Ig)A-predominant vasculitis. The differential diagnosis of ulcers and infarcts is extensive. Biopsy is often unrewarding because nonspecific changes present in established lesions may make interpretation difficult, but on occasion biopsy of ulcers or infarcts may result in a definitive diagnosis of vasculitis.

The neutrophilic dermatoses are a group of diseases inflammatory rather than infectious in origin, typified by pyoderma gangrenosum and Sweet's syndrome. These conditions have been associated with a variety of extracutaneous diseases, including RA. The classic pyoderma gangrenosum lesion is a rapidly appearing, large, destructive ulcer in which the border is undermined. The classic lesion of Sweet's syndrome is an erythematous, edematous plaque with a surface often described as mammillated, pseudovesicular, or microvesicular. Clinical appearances intermediate between these two have been described. For pyoderma gangrenosum, the differential diagnosis is usually that of conditions causing leg ulcer, and the diagnosis is mainly clinical, with biopsy primarily serving to exclude some of the other entities under consideration. For Sweet's syndrome, the differential diagnosis may include infections, halogenoderma, and other neutrophilic dermatoses. Biopsy often provides helpful supporting evidence. The mainstay of therapy for acute lesions of both conditions is systemic corticosteroids. For more persistent lesions, a variety of options may be considered, cyclosporine and infliximab being two of the more common. Colchicine or potassium iodide may be first-line therapies in patients with infections or contraindications to corticosteroids.

The term *rheumatoid neutrophilic dermatitis* has been given to describe chronic, erythematous, urticarial-like plaques that occur primarily on the distal arms.[9] Clinically and histologically, rheumatoid neutrophilic dermatitis is similar to Sweet's syndrome and may be a variant of it.

Palisaded neutrophilic and granulomatous dermatitis (PNGD) of connective tissue disease is an unusual condition or set of conditions for which consistent terminology is still evolving. As the name implies, the major bases for diagnosis of this entity are the histologic appearance and the occurrence in a patient with connective tissue disease, often RA.[10] The clinical appearance ranges from erythematous or flesh-colored papules that appear primarily on fingers and elbows to erythematous or flesh-colored linear cords on the trunk. Some authors classify the latter as interstitial granulomatous dermatitis with cutaneous cords or interstitial granulomatous dermatitis with arthritis (IGDA). Treatment of PNGD and IGDA can be challenging. PNGD may respond to dapsone or sulfapyridine. IGDA can be treated with anti-malarials or immunosuppressives, but evidence is based on case reports and small case series. Patients can progress to a severe deforming arthritis. In some cases, granuloma annulare and rheumatoid nodule may be in the differential diagnosis.

## JUVENILE RHEUMATOID ARTHRITIS/STILL'S DISEASE

The majority of patients with classic Still's disease manifest an exanthematous eruption coincident with daily fever spikes.[11] The lesions are evanescent, usually nonpruritic, erythematous macules occurring over the trunk, extremities, and face. The differential diagnosis includes viral exanthem, drug eruption, familial periodic fever syndromes, and rheumatic fever. It is not unusual for exanthems of any type to be more prominent during fevers, but it is not expected that viral exanthems and drug eruptions will clear completely between fever spikes. However, it should be noted that the eruption of erythema infectiosum (fifth disease) due to parvovirus B19 may resolve completely but reappear when the skin temperature rises, as with warm baths or

exercise. Adult-onset Still's disease is also typified by an evanescent erythematous, sometimes salmon-colored, eruption over the trunk and extremities, associated with high fever. Skin biopsy may be nonspecific. Some patients with adult-onset Still's disease have more persistent, pruritic lesions. The chronic lesions have been described as hyperpigmented plaques with a linear and rippled morphology. These lesions may exhibit a distinctive histology consisting of dyskeratotic keratinocytes in the upper epidermis, along with increased dermal mucin.[12]

Subcutaneous nodules may develop in both juvenile-onset and adult-onset Still's disease. The lesions tend to occur at the same sites of the body as do rheumatoid nodules in RA, but histologically they appear similar to nodules of rheumatic fever.

## LUPUS ERYTHEMATOSUS

| KEY POINTS |
|---|
| Patients with lupus erythematosus can have a wide variety of lupus-specific and lupus-nonspecific skin lesions. |
| Nonspecific skin lesions are more frequently seen in patients who have systemic lupus erythematosus or overlap syndromes. |
| Acute cutaneous lupus erythematosus is associated with a high risk for significant systemic disease. |
| Patients who present with other lupus-specific skin lesions have a low risk for moderate or severe systemic disease. |
| Subacute cutaneous lupus erythematosus is associated with antibodies to Ro/SSA and may sometimes be drug induced. |
| Neonatal lupus is associated with maternal IgG autoantibodies to Ro/SSA. Clinical findings may include cutaneous lesions, cardiac disease (usually complete heart block), hepatobiliary disease, or hematologic cytopenias. |
| The major skin findings in patients with Sjögren's syndrome consist of dryness and sequelae of dryness of the skin and mucous membranes. Vasculitis is also a relatively common finding. |
| Some patients with Sjögren's syndrome have subacute cutaneous lupus lesions or an annular erythematous eruption. |

The skin is involved at some time in the course of disease in the majority of patients with lupus erythematosus (LE), and skin lesions may be important in establishing the diagnosis. Some skin lesions are highly likely to be associated with "systemic" (i.e., extracutaneous) disease, whereas others may or may not be associated with extracutaneous disease. The phenomenon of lupus skin lesions occurring in the absence of systemic disease has previously been termed *discoid lupus* by some. However, dermatologists use this term to denote a specific type of skin lesion, regardless of presence or absence of systemic disease. It is the latter meaning of discoid lupus to which we refer in this chapter.

### Lupus-Specific Skin Lesions

James Gilliam classified cutaneous lesions as specific or nonspecific for lupus, with discoid lupus lesions an example of the former and palpable purpura an example of the latter.[13] Although this division of lesions is useful, sometimes a lupus-specific lesion occurs in a patient who has a primary autoimmune disease other than LE. For example, SCLE lesions may occur in patients whose primary condition is Sjögren's syndrome, and discoid lesions may be seen in a variety of conditions, such as mixed connective tissue disease. Many of the lupus-specific skin lesions can occur in patients who have no evidence of extracutaneous disease.

The characteristic morphologies of the various lupus-specific skin lesions are largely a function of the depth and intensity of the inflammatory infiltrate, presence or absence of epidermal basal cell damage, involvement of hair follicles, abundance of dermal mucin, and tendency to scar. In practice, there may be some overlap of these features, and there may be more than one type of lesion present in a given patient, which makes classification difficult. Because therapy for most of the lupus-specific lesions is similar, it is not always important to distinguish among the various types of lesions. However, it can be useful to identify conditions that are more likely to scar, to target more aggressive therapy, and to identify conditions that are highly likely or highly unlikely to be associated with systemic disease.

Acute cutaneous lupus (ACLE) lesions are typified by malar erythema, the classic butterfly rash (Figure 43-4). The inflammation tends to be superficial, with little propensity to scar. Precipitation or exacerbation of lesions by sun exposure is common, and lesions tend to be distributed on the sun-exposed face, neck, extensor arms, and dorsal hands, where the skin over the knuckles is relatively spared. Often the lesions are quite transient, but they may be persistent. When the face is severely affected, facial edema may be prominent. Oral lesions are often present concurrently. Acute eruptions with considerable focal basal cell damage can result in erythematous papules with dusky centers that clinically mimic erythema multiforme. The major importance of recognition of ACLE is its strong association with systemic disease. The differential diagnosis of malar rash may include several conditions. In some cases, the facial rash of ACLE may be difficult to distinguish from rosacea. Seborrheic dermatitis, atopic dermatitis, and photosensitive

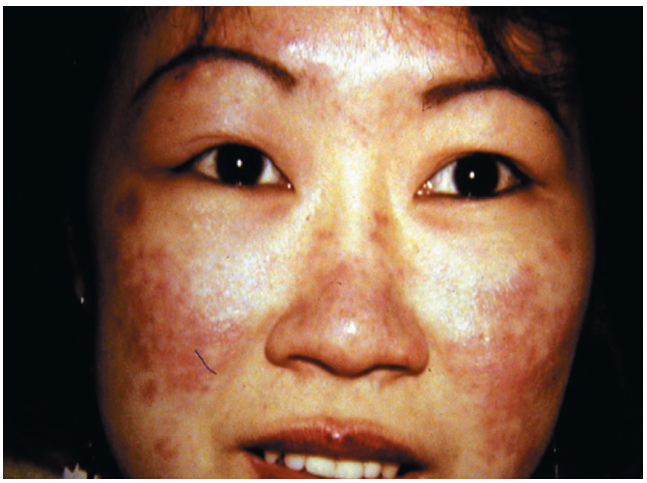

**Figure 43-4** Acute malar rash in a butterfly distribution in systemic lupus erythematosus.

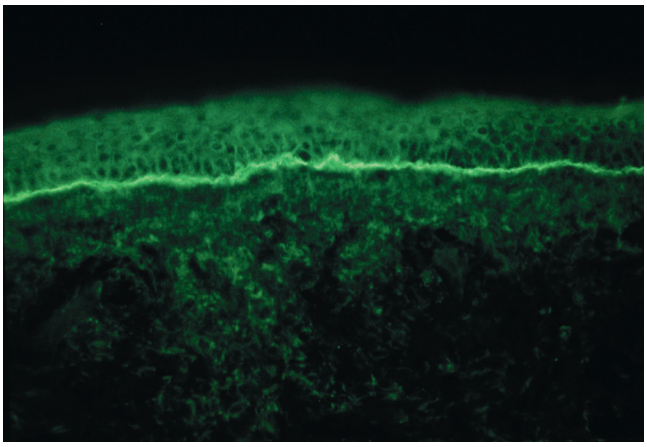

**Figure 43-6** Direct immunofluorescence (lupus band test) demonstrating IgG deposits at the dermal-epidermal junction.

eruptions, such as polymorphous light eruption and drug-induced photosensitivity, may also be considered. Dermatomyositis (DM) may cause a photosensitive facial erythema with edema similar to ACLE, although the erythema tends to be more violaceous. Persistent lesions on the neck and arms may be indistinguishable from SCLE. Discoid lupus lesions occasionally appear in a butterfly distribution, where they can result in disfiguring scarring. Skin biopsy is usually not performed on malar erythema because of its transient character, the scar resulting from biopsy, and the availability of other means of establishing the diagnosis of SLE. If a biopsy is done, it should be noted that DM and SCLE cannot be distinguished from ACLE by histology, and, also, that skin biopsy findings are sometimes nonspecific.

SCLE is a photosensitive eruption usually associated with anti-Ro/SSA autoantibodies.[14] Lesional morphology is of two main types: annular erythematous plaques and scaly erythematous psoriatic plaques. Lesions are distributed over sun-exposed skin of the arms, upper trunk, neck, and sides of the face (Figure 43-5). Inexplicably, the midfacial area is usually uninvolved. Fair-skinned individuals are preferentially affected. Lesions may resolve with hypopigmentation or even depigmentation, but they rarely scar. Several drugs, particularly hydrochlorothiazide and terbinafine, have been reported to induce SCLE.[15] The risk for systemic disease is not fully known, but perhaps 15% of patients with SCLE have or will develop significant systemic disease, often SLE, Sjögren's syndrome, or an overlap of the two disorders. Depending on the morphology of the lesions and the clinical presentation, the differential diagnosis may include psoriasis, tinea, polymorphous light eruption, reactive erythema, and erythema multiforme. Skin biopsy for routine histology is often helpful in establishing the diagnosis. The characteristic finding of skin biopsy for immunofluorescence is a particulate deposition of IgG in the epidermis (Figure 43-6), both in lesions and uninvolved skin.[16] This pattern can be reproduced in animal models by infusing anti-Ro, and thus immunofluorescence results provide information that duplicates serologic testing for anti-Ro.[17] The particulate epidermal pattern seen in normal skin does not indicate an increased risk for SLE. However, increased risk is indicated by the finding of granular deposits of IgG at the dermal-epidermal junction of normal skin (the nonlesional lupus band test). It should be noted that many immunofluorescence laboratories do not routinely report particulate epidermal staining.

**Figure 43-7** Discoid lupus erythematosus of the scalp, with scarring alopecia and central hypopigmentation. *(Courtesy Dr. Nicole Rogers, Tulane University School of Medicine, New Orleans.)*

Discoid lupus erythematosus (DLE) lesions are the most common of the persistent lupus-specific skin lesions. Population-based studies indicate that cutaneous lupus, to include DLE and SCLE, has an incidence similar to that of SLE.[18,19] Active DLE lesions are erythematous papules and plaques that, when palpated, feel indurated because of the substantial numbers of inflammatory cells that infiltrate the dermis. Involvement of hair follicles may be grossly evident as follicular plugs and scarring alopecia. Dyspigmentation is common, often with hypopigmentation or even depigmentation in the center and hyperpigmentation at the periphery (Figure 43-7). Visible scale is common and occasionally is pronounced in a clinical variant called *hypertrophic DLE*. In established lesions, scarring may be disfiguring. Lesions tend to occur on the scalp, ears, and face but may be widespread and occasionally involve mucosal surfaces. It is unusual to have lesions below the neck in the absence of lesions above

the neck. Sun exposure may exacerbate DLE in some cases, but the presence of lesions in sun-protected areas of the scalp and ears and the frequent absence of a history of photosensitivity indicates that sun exposure is probably not a trigger in every instance. There are case reports of squamous cell carcinoma developing in patients with established DLE lesions. In a patient who presents with DLE lesions only, the risk for development of moderate to severe systemic symptoms is probably approximately 5% to 10%, although mild systemic symptoms such as arthralgias are relatively common. As many as 15% to 20% may meet the criteria for SLE, but many do so solely on the basis of mucocutaneous findings.[20] The differential diagnosis of DLE lesions is often that of conditions that exhibit intense lymphocytic or granulomatous infiltrates such as sarcoid, Jessner's lymphocytic infiltrate, granuloma faciale, polymorphous light eruption, lymphocytoma cutis, and lymphoma cutis. In the scalp, lichen planopilaris and other scarring alopecias may be considered. Skin biopsy for routine histology often establishes the diagnosis definitively. In more difficult cases, biopsy for immunofluorescence may provide additional supporting diagnostic information. Lesions are expected to have granular deposits of Igs at the dermal-epidermal junction. Unless there is concomitant systemic disease, normal skin is expected not to have Ig deposits.

Tumid lupus (TLE) skin lesions are similar to DLE lesions in that they are erythematous indurated papules and plaques with a substantial lymphocytic infiltrate. Unlike DLE, though, the lesions do not exhibit epidermal abnormalities, follicular involvement, or scarring. Considerable mucin is present in the dermis, which gives the lesions a somewhat boggy look and feel. In some reports, lesions are most common on the face and may be reproduced by phototesting.[21] The risk for SLE appears to be low, and Ig deposits are not generally present in skin biopsies. Jessner's lymphocytic infiltrate and other lymphocytic and granulomatous infiltrative conditions (see earlier) are in the differential diagnosis. Skin biopsy for routine histology is valuable in establishing the diagnosis, with the exception of reliably distinguishing TLE from Jessner's lymphocytic infiltrate. Some have argued that Jessner's lymphocytic infiltrate and TLE are one and the same, and it might reasonably be argued that what is called TLE is not appropriately classed as a form of chronic cutaneous LE but rather as an independent entity. However, the presence of TLE lesions in some patients with lupus is evidence to the contrary.

Lupus panniculitis (LEP) lesions have inflammation in the subcutaneous tissue, resulting in deep indurated plaques that become disfiguring, depressed areas (Figure 43-8). Usual sites of involvement are the face, scalp, upper trunk, breasts, upper arms, buttocks, and thighs. The risk for SLE is not known precisely, but clearly some patients with LEP have or will develop SLE. The differential diagnosis is that of the panniculitides, but the distribution exhibited in LEP is unusual for most other conditions that cause panniculitis. The correlation of clinical with histologic findings usually serves to establish the diagnosis.

Some unusual variants of cutaneous lupus are chilblain lupus (red or dusky plaques on colder areas of skin, such as fingers, toes, nose, elbows, knees, and lower legs), cutaneous lupus/lichen planus overlap, and a bullous eruption associated with autoantibodies to type VII collagen or other basement membrane zone proteins. Not all bullae related to lupus are due to autoantibodies to basement membrane proteins, however. It is not unusual for bullae to develop in the patient simply from intensive destruction of the basal cell layer in ACLE, SCLE, or, rarely, DLE.

**Figure 43-8** Lupus profundus (panniculitis) with extensive atrophy.

Treatment of the lupus-specific lesions is relatively similar for most of the subtypes, with some exceptions and modifications.[22] Sun protection is critical for lesions that are initiated or exacerbated by sun exposure. Many or most patients underestimate the amount of sunscreen needed to apply, the potential damage of the seemingly minimal exposure one has in the course of day-to-day activities, and the value of protective clothing. Tobacco use appears to be an exacerbating factor and can prevent response to therapy.[23] Topical therapy is often used to avoid side effects of systemic medications or to provide adjunctive therapy, although topical agents are unlikely to be beneficial if the disease process is deep, as in panniculitis. Topical or intralesional corticosteroids are the most often used local therapy, but there are some reports of benefit from topical calcineurin inhibitors and topical retinoids. The first-line systemic medication for cutaneous lupus is antimalarial therapy, most often hydroxychloroquine. For skin disease not responsive to hydroxychloroquine, changing to chloroquine or adding quinacrine has been helpful in some patients. For antimalarial-resistant skin disease, a wide variety of medications have been used, but there is no clear second choice when patients have not responded to anti-malarials . When evaluating response to therapy, it is important for the clinician to distinguish active disease, as manifested by erythema or development of new lesions, from "damage," as exemplified by scarring or dyspigmentation. Although dapsone is arguably not helpful in most types of cutaneous lupus, it may be helpful in neutrophil-predominant bullous eruptions.[24] Measures to keep the skin warm may be useful for chilblains lupus.

## Nonspecific Cutaneous Lesions

A wide variety of lupus nonspecific skin lesions has been reported. Many of these, such as vasculitic lesions, are cutaneous clues to the possibility of extracutaneous disease.

Livedo reticularis is noteworthy in this regard. The netlike erythema of livedo reticularis is a vascular phenomenon caused by lowered oxygenation at the periphery of the area supplied by a particular vessel. This can simply be due to vasoconstriction, such as occurs in a cold environment, and thus can be a benign finding. If livedo is more prominent than usual, not corrected by warming, and persistent, it can indicate lowered flow caused by pathology such as vasculitis, atherosclerotic disease, or sludging. In lupus, livedo reticularis may be a sign of the presence of anti-phospholipid antibodies.[25]

Other lupus nonspecific skin lesions include Raynaud's phenomenon, palmar erythema, periungual telangiectasia, alopecia, erythromelalgia, papulonodular mucinosis, and anetoderma. Sclerodactyly, calcinosis, and rheumatoid nodules have been reported but may be more likely in overlap syndromes than in SLE.

## NEONATAL LUPUS SYNDROME

Neonatal lupus erythematosus (NLE) is associated with maternal IgG autoantibodies to Ro/SSA and La/SSB.[26] Affected children may have cutaneous lesions, cardiac disease (notably complete heart block and/or cardiomyopathy), hepatobiliary disease, or hematologic cytopenias. Most children have only one or two features of the disease. Similar to the anti-Ro/SSA-associated SCLE of adults, the skin lesions are often photosensitive, have relatively superficial inflammatory infiltrates, and do not tend to scar. The lesions usually appear in infants at a few weeks of age but have been noted at birth in several cases. The natural history of the skin disease is that the lesions last for weeks or months and resolve spontaneously, usually leaving no residuum. In a few cases, persistent telangiectasias have been noted. Individual lesions appear as erythematous annular papules or plaques. Lesions are usually more numerous and more intensely inflamed on the face and scalp, but may additionally occur on the patient's trunk and extremities. Confluent periorbital erythema, which gives the appearance of an erythematous mask, is common and diagnostically helpful. Even though the skin disease resolves and most children without extracutaneous involvement remain otherwise healthy, there is a possibility that children who have had NLE are at increased risk for autoimmune disease later in childhood.[27]

Differential diagnosis of the skin lesions may include reactive erythema, drug eruption, erythema multiforme, and urticaria. Annular NLE lesions usually have little or no scale, unlike the annular lesions of tinea. In areas where there is intense destruction of the basal cell layer, lesions may be crusted and look similar to bullous impetigo. Treatment of skin lesions consists largely of sun protection and mild topical steroids.

The pathogenesis of lupus is covered elsewhere, but it is noteworthy that SCLE-like, anti-Ro/SSA–associated skin lesions may occur in neonates, but other lupus-specific skin lesions do not appear to be maternally transmissible.

## SJÖGREN'S SYNDROME

The most common mucocutaneous findings of Sjögren's syndrome are related to glandular dysfunction. Lacrimal gland dysfunction causes dryness and irritation of the eyes and can lead to keratitis and corneal ulceration. Salivary gland dysfunction causes dry mouth and may result in angular cheilitis and numerous dental caries. Vaginal xerosis may cause burning and dyspareunia. The skin may be dry, cracked, and pruritic. Mildly dry mucous membranes and even severely dry skin may be present in a substantial percentage of healthy individuals who live in dry climates, thus the findings should be interpreted in the context of the setting. In Japanese patients with Sjögren's syndrome, an annular erythema has been described that is somewhat reminiscent of annular SCLE or annular lesions of NLE, although more indurated.[28]

Vasculitis is a relatively common finding. In one series of 558 patients with primary Sjögren's syndrome, 52 had vasculitis, typically involving the small vessels. In most cases, lesions were purpuric, but in some, urticarial vasculitis was the clinical presentation. Patients with cutaneous evidence of vasculitis generally had more severe systemic disease.[29]

## DERMATOMYOSITIS

**KEY POINTS**

- **Patients with DM may present with only skin or skin and lung involvement in the absence of muscle disease.**
- **Patients with DM often have erythema on the upper eyelids, over joints on the hands, on the elbows, and in the malar area that extends to involve the nasolabial fold.**
- **Skin biopsies are important to rule out other diseases that can mimic DM, such as psoriasis, eczema, or multicentric reticulohistiocytosis. Clinical-pathologic correlation is critical because skin biopsies of cutaneous lupus and DM can be identical.**
- **Patients with involvement of the sides of the fingers are more likely to have interstitial lung disease. All patients with DM should have screening pulmonary function tests.**

The current American College for Rheumatitis (ACR) criteria for DM do not recognize the existence of amyopathic dermatomyositis (ADM). This omission has led to a problem in diagnosing patients with predominantly skin involvement with DM. Revised classification criteria[30] are currently addressing this problem. ADM, or dermatomyositis sine myositis, refers to classic cutaneous manifestations of DM without evidence of inflammatory myopathy. ADM has also been defined as biopsy-proven cutaneous findings of classic DM that occur for 6 months or longer without any clinical evidence of proximal muscle weakness, serum muscle enzyme abnormalities, or abnormal muscle testing. This latter definition excludes any patient treated with systemic immunosuppressive therapy for 2 or more consecutive months during the first 6 months of cutaneous manifestations of DM because therapy could suppress clinically significant myositis. It also excludes any patient using drugs that are associated with DM-like skin changes (e.g., hydroxyurea).[31]

The most common cutaneous manifestations of active DM include Gottron's papules (Figure 43-9) and Gottron's sign, which are pathognomonic of DM. Other characteristic

**Figure 43-9** Gottron's papules over the interphalangeal joints in dermatomyositis.

**Figure 43-10** Heliotrope eruption of dermatomyositis with characteristic edema.

findings of DM include heliotrope rash of the periorbital and upper eye area (Figure 43-10), V- or shawl-shaped macular erythema over the chest and back, cuticular overgrowth, and periungual telangiectasias. Patients with active disease can have widespread erythema over the trunk and extremities, with accentuation of the extensor arms and legs, as well as lateral thighs. Erythema and scale of the scalp can result in extensive alopecia. Hyperkeratosis of the palmar and lateral surfaces of the fingers, called *mechanic's hands*, can be associated with anti–Jo-1 autoantibodies and interstitial lung disease. Rarely, patients can have a panniculitis. Vasculopathy, with livedo reticularis and ulceration, can occur. Itching can result in excoriations and lichenification. Damage lesions include postinflammatory hyperpigmentation, poikiloderma, calcinosis, lipoatrophy, and depressed scars.[32] Poikiloderma is a descriptive term for a pattern of finely mottled white areas and brown pigmentation, telangiectasia, and atrophy.

Skin biopsy from a patient with cutaneous DM is identical to that seen with cutaneous lupus erythematosus. A diagnosis of DM is made by clinical-pathologic correlation and does not need to include muscle disease. In the absence of clinical muscle findings, the workup for DM should include muscle enzyme testing, pulmonary function testing, chest radiograph, electrocardiogram, and evaluation for underlying malignancy. Patients with ADM have the same incidence of pulmonary involvement as classic DM, and approximately 25% of patients have evidence of pulmonary fibrosis on high-resolution CT.[33] There is an increased risk for malignancy in adult patients with DM, including ADM. The most frequent malignancies are lung, ovarian, pancreatic, stomach, colorectal, and non-Hodgkin's lymphoma.[34] The increased risk of malignancy occurs for at least 5 years after the diagnosis of DM, and thus patients should receive routine cancer screening during that time.[35] Patients with DM frequently experience a delay in obtaining a diagnosis, and the presence of photosensitivity, malar rash, oral ulcers, and a positive anti-nuclear antibody (ANA) test means that they frequently are misdiagnosed as having SLE, having met the current criteria for the disease.

The patients with both skin and muscle disease frequently experience resolution of their muscle disease after aggressive treatment with glucocorticoids, with or without immunosuppressives. Patients are sometimes treated with intravenous immunoglobulin (IVIG), cyclosporine, or tacrolimus. Patients with AMD or residual skin disease after treatment often benefit from hydroxychloroquine. Patients who do not improve with a single antimalarial can benefit from the addition of quinacrine or a switch from hydroxychloroquine to chloroquine.[36] Immunosuppressives such as methotrexate, azathioprine, or mycophenolate mofetil can be of additive benefit for patients with resistant skin disease. IVIG can be of benefit for skin findings of DM, and studies related to the role of biologics in treatment are ongoing.[37]

## SCLERODERMA AND OTHER SCLEROSING CONDITIONS

**KEY POINTS**

- **Scleroderma can occur as localized or systemic disease.**
- **The localized form of the disease occurs as localized or generalized morphea, linear scleroderma, or facial hemiatrophy, otherwise known as *Parry-Romberg syndrome*.**
- **Linear forms of the disease occur more often in children, whereas morphea and scleroderma are more common in adults.**
- **Eosinophilic fasciitis involves the fascia below the fat and can be associated with eosinophils in the tissue and is more responsive to glucocorticoids than localized or systemic scleroderma.**
- **Some fibrosing conditions, including scleromyxedema and POEMS, are associated with monoclonal gammopathies.**
- **Nephrogenic systemic fibrosis is related to gadolinium exposure in patients with decreased renal function. The histology is indistinguishable from scleromyxedema.**

### Morphea

Scleroderma can occur as localized or systemic disease. The localized form of the disease occurs as localized or generalized morphea, linear scleroderma, or facial hemiatrophy,

otherwise known as *Parry-Romberg syndrome*. Linear scleroderma can occur over the forehead, in a variant called *en coup de sabre* (Figure 43-11). Morphea is seen more in adults, with increased incidence with advancing age, whereas linear scleroderma occurs more frequently in children and adolescents.[38] Although remissions are reported to occur in 3 to 5 years, ongoing clinical activity or reactivation is not unusual.

Localized scleroderma patients typically lack sclerodactyly, Raynaud's phenomenon, or internal organ involvement. The level of involvement in localized scleroderma can be in the dermis (morphea), fat (subcutaneous morphea), fat and fascia (morphea profundus), and fascia (eosinophilic fasciitis). Morphea typically has round and/or oval, irregular plaques that are initially dull red/violaceous, smooth, and indurated. They frequently progress to chalky, white atrophic lesions, although some patients have residual hyperpigmentation overlying the lesions. Morphea can have different presentations, including an overlap with lichen sclerosus et atrophicus, in which there are flat-topped papules that coalesce to form a white plaque, sometimes combined with a deeper morphea lesion. Some lesions are small and oval, known as *guttate morphea*. Occasionally, patients with localized scleroderma overlap with other autoimmune diseases such as SLE. Many mimics of morphea exist, including radiation-induced morphea, injection-induced morphea-like lesions, morphea-like Lyme disease (seen in Europe), eosinophilia-myalgia syndrome, toxic oil syndrome, and, more recently, nephrogenic systemic fibrosis (NSF).

Linear scleroderma is frequently located on the lower limbs, upper limbs, frontal head area, and anterior trunk. It is frequently unilateral and can result in joint deformity, joint contractures, and limb atrophy. Some cases are associated with seizures or other focal neurologic symptoms. Parry-Romberg syndrome can occur in the first or second decade of life and leads to unilateral facial atrophy in 95%. Half of patients with linear scleroderma start with en coup de sabre and progress to have soft tissue involvement in the upper face. Patients can have seizures, headaches, visual changes, and atrophy of the salivary glands and hemiatrophy of the tongue on the same side as the facial atrophy. Any reparative surgical treatment should be timed to occur no sooner than 1 year after cessation of the ongoing atrophic process. ANAs are positive 46% of the time in cases of localized scleroderma. A positive ANA correlates with disease severity.[39] A peripheral eosinophilia and hypergammaglobulinemia can be seen.

Treatment of localized scleroderma includes protection from trauma and cold, anti-malarials (hydroxychloroquine alone, hydroxychloroquine and quinacrine together, or chloroquine with or without quinacrine), low-dose prednisone for eosinophilic fasciitis, topical calcipotriene, methotrexate, and mycophenolate mofetil. Phototherapy with narrow-band UVB, UVA1, PUVA, and topical photodynamic therapy has also been used.[40]

**Figure 43-11** Linear scleroderma of the forehead. *(Courtesy Dr. Victoria Werth, University of Pennsylvania Department of Dermatology and Philadelphia Veterans Administration Medical Center, Philadelphia.)*

## Systemic Scleroderma

Patients with early limited cutaneous scleroderma have Raynaud's phenomenon for many years, minimal constitutional symptoms, puffy fingers, limited skin thickening, and anticentromere antibody. Patients with early diffuse cutaneous scleroderma frequently have delayed Raynaud's, acute onset, many constitutional symptoms, arthralgias, tendon friction rubs, swollen puffy hands, and early diffuse skin thickening. They may have anti–Scl-70 antibody, as well as anti–RNA polymerase III. The major and minor criteria for diffuse cutaneous scleroderma include many skin findings. Major criteria include proximal scleroderma. Minor criteria include sclerodactyly (Figure 43-12), digital pitting and scars of the fingertips, loss of substance of the finger pad, and bibasilar pulmonary fibrosis.[41] New criteria to identify patients with early disease have been proposed.[42] Ischemia and skin changes in systemic scleroderma can result in skin ulcers. Therapies used in the cutaneous treatment of systemic scleroderma include D-penicillamine, methotrexate,

**Figure 43-12** Sclerodactyly with flexion contractures.

cyclophosphamide, mycophenolate mofetil, photopheresis, and hematopoietic stem cell transplant.[43,44] Treatment of Raynaud's phenomenon is covered elsewhere. There are reports of bosentan, an endothelin receptor antagonist, and phosphodiesterase inhibitors, such as sildenafil, being helpful in the treatment of skin ulcers.[45,46] Patients who have pruritus may benefit from systemic antihistamines.

## Eosinophilic Fasciitis

Eosinophilic fasciitis (EF) involves inflammation of the fascia overlying muscle and results in swelling of the extremities, followed by fibrosis and contractures. The digits are typically spared. There is often a rapid onset of disease activity, particularly following physical exertion. A contaminant of L-tryptophan was associated with an EF-like disease in the early 1990s.[47] Approximately 30% of EF patients have morphea concurrently.

Diagnosis is normally based on a deep, usually excisional biopsy of the skin that includes fascia. There are inflammatory cells among collagen bundles, thickening of collagen, sclerosis of the dermis and fat/fascia, and absent sweat glands and hair. MRI of active EF demonstrates thickening of the fascia overlying the muscle, hyperintense signal within the fascia on fluid-sensitive sequences, and fascial enhancement after IV contrast.[48]

## POEMS Syndrome

POEMS syndrome includes polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes. To be diagnosed with POEMS, a patient must have polyneuropathy and a monoclonal plasmaproliferative disorder, along with one other minor criterion that includes sclerotic bone lesions, Castleman's disease, organomegaly, edema, endocrinopathy, papilledema, or skin changes. Other associated findings may include ascites, pleural effusions, thrombocytosis, fingernail clubbing, and white nails. The sensorimotor polyneuropathy has both demyelinating and axonal features and is slowly progressive and debilitating in most cases. Organomegaly may be hepatosplenomegaly or lymph node enlargement. Endocrinopathies include diabetes, impotence, gynecomastia, and hypothyroidism. The monoclonal (M) protein abnormality consists of IgA or IgG heavy chains with λ light chains. The skin changes may consist of hyperpigmentation, hypertrichosis, hyperhidrosis, skin thickening, telangiectasia, and glomeruloid hemangiomas.[49] Treatment with corticosteroids, low-dose alkylators, lenalidomide, and high-dose melphalan and autologous peripheral blood stem cell transplantation has been reported to be successful.[50,51]

## Scleromyxedema

Scleromyxedema is a rare disorder frequently characterized by dysproteinemia and widespread skin changes. The paraprotein stimulates fibroblast production of mucin, suggesting a causal role and a rationale for lowering it. Patients have waxy papules on the face, neck, upper trunk, forearms, hands, and thighs that become confluent and occur in association with underlying sclerosis, which can lead to joint contractures, sclerodactyly, and carpal tunnel syndrome. Common extracutaneous manifestations include upper gastrointestinal dysmotility, muscle weakness, joint contractures, and neurologic symptoms, such as seizures, encephalopathy, coma, and obstructive or restrictive pulmonary disease. Ninety percent of patients have a monoclonal gammopathy, most frequently IgGλ, but occasionally IgGκ.[52,53]

Skin biopsy shows mucin deposition and a proliferation of fibroblasts in the upper dermis. Treatment has included prednisone, IVIG, PUVA, systemic retinoids, thalidomide, lenalidomide, interferon (IFN) alfa-2a, plasmapheresis, photopheresis, low-dose melphalan, and high-dose dexamethasone.[52] Chemotherapeutic agents such as melphalan, cyclosporine, cladribine, cyclophosphamide, methotrexate, and chlorambucil have been used. Successful remission after autologous stem cell transplantation has been reported.[54]

## Nephrogenic Systemic Fibrosis

NSF is a relatively new illness that occurs in patients with renal disease; most of the patients have undergone dialysis for renal failure.[55] NSF presents as either a morphea-like disease or a more diffuse acral sclerosis. Morphea-like presentations include ill-defined indurated plaques, with islands of sparing and finger-like projections that involve lower more than upper extremities. More diffuse confluent acral sclerosis, sometimes with truncal involvement, can occur. There are often yellow plaques on the conjunctiva. Patients can experience pain, severe itching, joint contractures, fibrosis and calcification of the skin, subcutaneous tissue, fascia, muscle, myocardium, lungs, renal tubules, and testes. Patients typically do not have Raynaud's syndrome. Skin biopsy is identical to that seen with scleromyxedema, with stellate fibroblasts, glycosaminoglycans, and thickening of collagen.[56] Transforming growth factor (TGF)-β is increased in lesional skin.[57] There is no proven effective therapy, and prognosis depends on the extent, rapidity of skin involvement, and severity of the systemic disease.[57] Treatments that have been reported to potentially help include plasmapheresis, IVIG, immunosuppressives, glucocorticoids, IFN-α, thalidomide, PUVA, UVA1, photopheresis, and imatinib mesylate.[58] Recent studies suggest a strong association of NSF with gadolinium exposure, with some cases of delayed onset after exposure.[59]

# PRIMARY VASCULITIS INVOLVING THE SKIN

**KEY POINTS**

- **In cutaneous diseases, the term *vasculitis* is typically reserved for lesions that histologically show damage to vessel walls and a neutrophilic or granulomatous infiltrate.**
- **The major determinant of the clinical appearance is the size of the vessel affected.**
- **Small vessel vasculitis unassociated with rheumatic diseases is often short lived and limited to the skin.**
- **A characteristic lesion of cutaneous small vessel vasculitis is palpable purpura in dependent areas of the body. It is common for the majority of lesions to be nonpalpable.**

**Systemic corticosteroids are not routinely indicated for skin-limited disease.**

**Urticarial vasculitis lesions are morphologically similar to urticaria but more long lasting. Hypocomplementemic urticarial vasculitis is associated with a higher risk of significant internal disease.**

**Two major forms of small vessel vasculitis in children are Henoch-Schönlein purpura, which is characteristically associated with internal involvement, and acute hemorrhagic edema of infancy, a dramatic-appearing but benign and self-limited condition.**

**Skin biopsy of granulomatosis with polyangiitis and of eosinophilic granulomatosis with polyangiitis often shows small vessel vasculitis rather than true granulomatous vasculitis.**

**A variant of PAN, termed *benign cutaneous PAN* ,or *primarily cutaneous PAN* is characterized by tender subcutaneous nodules and livedo reticularis.**

**Figure 43-13** Leukocytoclastic vasculitis demonstrating nonblanching, purpuric macules.

In cutaneous diseases, *vasculitis* is a term typically reserved for lesions characterized by damage to vessel walls and a neutrophilic or granulomatous infiltrate. Classification, pathogenesis, diagnostic evaluation, and therapy are covered elsewhere in the text. In this chapter, the focus is on the skin findings and differential diagnosis. The primary determinant of the appearance is the size of the vessel affected.

## Cutaneous Small Vessel Vasculitis and Its Variants

Cutaneous small vessel vasculitis is a rather common condition with characteristic histologic findings of fibrinoid necrosis of vessel walls, a neutrophil-predominant infiltrate, and leukocytoclasis (i.e., fragmented nuclei resulting from degeneration of neutrophils).[60] In the skin, the vessels involved are in the dermis, and damage to these vessels results in lesions of a characteristic size. The lesions are both erythematous and purpuric and are distinctly palpable if there are sufficient numbers of neutrophils in the lesion. On physical examination, it may be helpful for the physician to palpate several lesions because it is common for the majority of the lesions to be nonpalpable. The usual diameter of the purpuric papules is approximately 0.3 to 0.6 cm, although smaller and larger lesions may be observed (Figure 43-13). Discrete lesions have a round shape. The center may look dusky, pustular, or ulcerated, or it may appear as a hemorrhagic vesicle. Larger ulcerations may occur when lesions coalesce. Particularly in larger lesions, the devitalized tissue may be a focus for secondary bacterial infection. Lesions tend to occur in dependent areas. Thus for ambulatory patients, lesions are most numerous on the lower legs. Koebnerization, the appearance of lesions along lines of trauma, such as scratches, is sometimes observed.

As mentioned under the discussion of rheumatoid vasculitis, the differential diagnosis of purpuric or petechial lesions may include stasis dermatitis, pigmented purpuric dermatosis, platelet dysfunction or deficiency, petechial drug eruptions, viral exanthems, emboli (cholesterol, septic), thromboses, and sludging. Skin biopsy is often helpful in establishing the diagnosis of small vessel vasculitis, especially if an early lesion is sampled. Immunofluorescence of an early lesion may establish whether the vasculitis is IgA predominant.

Small vessel vasculitis unassociated with connective tissue disease and not IgA predominant is sometimes called *hypersensitivity vasculitis*. It is often apparently confined to the skin and therefore has a good prognosis. In some cases, infection or drugs may be implicated, but often no definitive initiating event is discovered. Therapy is directed first toward treating the underlying cause, if a cause is found. If there is no significant extracutaneous disease, treatment is often symptomatic. Leg elevation, compression stockings, and reduction of activity may be helpful. Nonsteroidal anti-inflammatory drugs (NSAIDs) or antihistamines are sometimes used. Systemic corticosteroids are not routinely indicated for skin-limited disease. For patients with persistent disease confined to the skin, colchicine and dapsone have each been used with some success.[61]

A common variant of small vessel vasculitis is Henoch-Schönlein purpura (HS purpura). HS purpura occurs commonly in children and is often associated with extracutaneous findings of gastrointestinal or renal involvement. The typical lesion of IgA-predominant small vessel vasculitis is an erythematous or urticarial macule or papule that evolves rapidly into palpable purpura. It has been noted that IgA-predominant vasculitis in particular may display superficial plaques of palpable purpura or a retiform configuration of lesions.[62] The most reliable means of establishing that the vasculitis is IgA predominant is biopsy for immunofluorescence. IgA-predominant vasculitis is not unusual in adults. Compared with the presentation in children, there is a lower association with preceding upper respiratory infection and higher association with medication use.

Mixed cryoglobulinemia can present as a small vessel vasculitis. Additional skin findings that may occur include livedo reticularis, urticarial papules, cold urticaria, Raynaud's syndrome, acrocyanosis, leg ulcers, and digital ulceration or gangrene. Hepatitis C is a frequent association. Patients with type I monoclonal cryoglobulinemia may more often have purpura caused by cryogelling rather than a true vasculitis.

A distinct subset of patients with small vessel vasculitis has lesions that are primarily urticarial rather than purpuric.

The main diagnosis in the clinical differential is urticaria. Individual lesions of urticaria tend to be short lived, usually less than 24 hours, whereas individual lesions of urticarial vasculitis tend to last several days. Additional skin findings may include angioedema, livedo reticularis, nodules, and bullae. In some lesions, foci of purpura may be observed. Urticarial vasculitis has been classified into two groups: normocomplementemic and hypocomplementemic. Extracutaneous disease is more likely to occur in the hypocomplementemic group, and some of these patients have underlying SLE. It has been proposed that there is a distinctive subset of the hypocomplementemic group characterized by IgG antibodies to C1q, angioedema, ocular inflammation, arthritis, obstructive pulmonary disease, and renal disease. The pulmonary disease tends to be severe and life threatening. This subset has been termed *hypocomplementemic urticarial vasculitis syndrome*.[63,64]

Erythema elevatum diutinum is an unusual form of small vessel vasculitis that is characterized by erythematous or violaceous papules, plaques, and nodules over the dorsal hands, ears, knees, heel, and buttocks. In the clinical differential diagnosis are Sweet's syndrome, multicentric reticulohistiocytosis, sarcoidosis, and lymphoma, among others. With time, fibrosis often occurs. Established lesions may be disfiguring and may have an appearance somewhat reminiscent of keloids. Although significant extracutaneous involvement is not expected and many patients are otherwise well, erythema elevatum diutinum has been reported in association with various autoimmune, infectious, and hematologic conditions, including streptococcal infection, paraproteinemia, inflammatory bowel disease, RA, SLE, and HIV. For active skin lesions, dapsone is the usual treatment.[65] Intralesional corticosteroids are sometimes used for fibrotic lesions.

Acute hemorrhagic edema of childhood is an uncommon but generally benign and self-limited form of vasculitis usually occurring in children younger than 2 years, commonly preceded by an upper respiratory infection or medication.[66] The clinical appearance may be dramatic, with large purpuric plaques on the face, ears, and extremities. On the basis of the appearance of the skin lesions, meningococcemia is sometimes suspected but the child with acute hemorrhagic edema appears relatively healthy. Generally there is no extracutaneous involvement. Treatment is symptomatic.

## Granulomatous Vasculitides

Skin lesions are occasionally the presenting feature of granulomatosis with polyangiitis.[67] The most common type of lesion is palpable purpura, with or without necrosis. Many other types of lesions have been noted, including papules, ecchymoses, hemorrhagic bullae, necrotic papules, subcutaneous nodules, and ulcers. Ulcerative lesions may be similar in appearance to pyoderma gangrenosum, although lacking an undermined border. Oral ulcers are relatively common but nonspecific in appearance. A more specific oral finding is hypertrophic gingival inflammation with petechiae.

Skin biopsy is sometimes helpful diagnostically, but unfortunately, biopsies are often nonspecific or show small vessel vasculitis. True granulomatous vasculitis is not often observed in skin specimens. Extravascular granulomatous inflammation is sometimes noted, and may be more likely to occur in nonpurpuric papules or nodules than in palpable purpura.

Differential diagnosis of the skin lesions includes other small vessel vasculitides, particularly when cutaneous lesions consist of palpable purpura and the biopsy finding is leukocytoclastic vasculitis. If granulomatous inflammation is observed, the differential diagnosis may include eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome), polyarteritis nodosa, microscopic polyangiitis, RA, SLE, infection, lymphoproliferative disorders, chronic active hepatitis, erythema nodosum, granuloma annulare, and inflammatory bowel disease.

Patients with eosinophilic granulomatosis with polyangiitis characteristically present with respiratory symptoms, but skin lesions are common during the vasculitic phase of the disease.[68] Hemorrhagic lesions ranging from petechiae to palpable purpura to ecchymoses, cutaneous nodules with or without ulceration, subcutaneous nodules, and nonspecific erythematous eruptions are most common. As with granulomatosis with polyangiitis, hemorrhagic lesions tend to show small vessel vasculitis on biopsy, and nodules are more likely to demonstrate granulomas. The clinical and histologic differential diagnoses often include polyarteritis nodosa, granulomatosis with polyangiitis, and microscopic polyangiitis. As alluded to earlier, the histologic finding of Churg-Strauss granuloma is not specific for eosinophilic granulomatosis with polyangiitis, and may be seen in several entities. Large numbers of eosinophils in the biopsy may be diagnostically helpful but are not definitive. Hypereosinophilic syndrome may share clinical and laboratory features with eosinophilic granulomatosis with polyangiitis, but vasculitis is not characteristic.

## Polyarteritis Nodosa and Related Conditions

Classic polyarteritis nodosa (PAN) and microscopic polyangiitis have historically been classified as PAN but appear to be distinct conditions distinguishable in part by the size of vessels affected. Classic PAN involves medium-sized vessels, whereas microscopic polyangiitis primarily involves vessels ranging in size from capillaries to arterioles.

Cutaneous findings of classic PAN represent damage downstream of the affected vessel and consist of ulceration, digital gangrene, ecchymoses from vessel rupture, livedo reticularis, and subcutaneous nodules that may follow the course of arteries. Because the affected vessel is proximal to the skin, skin biopsy is likely to show nonspecific findings.

The skin findings of microscopic polyangiitis reflect the smaller size of vessels affected. Petechiae, palpable purpura, purpuric plaques, erythematous nodules, and ulcerations may be observed. There have been some reports of livedo reticularis in association with microscopic polyangiitis The cutaneous pathology is that of a leukocytoclastic vasculitis, but, in contrast to many of the small vessel vasculitides previously discussed, may involve small arterioles. The differential diagnosis is mainly that of other small vessel vasculitides. Size of vessels affected, anti-neutrophilic cytoplasmic antibody (ANCA) positivity, paucity or absence of antibody deposits in vessels, and spectrum of extracutaneous

involvement aid in distinguishing microscopic polyangiitis from other vasculitides.

There is a variant of PAN termed *benign cutaneous PAN* or, perhaps more accurately, *primarily cutaneous PAN*. In this condition, arterioles in the subcutaneous fat and lower dermis are affected, and the presentation is often that of tender subcutaneous nodules and livedo reticularis. Associations with Crohn's disease, hepatitis B, and hepatitis C have been reported. Clinically, panniculitides such as erythema nodosum and erythema induratum may be considered, although livedo reticularis is not expected. A biopsy for diagnosis should include subcutaneous fat. Even after biopsy, microscopic polyangiitis may be difficult to exclude. Although relatively little information is available concerning ANCA in cutaneous PAN, a negative ANCA is more consistent with cutaneous PAN than with microscopic polyangiitis. Although the outcome is benign, the course is often chronic and relapsing. Therapy is typically conservative and may consist of intralesional corticosteroids, NSAIDs, low-dose methotrexate, dapsone, or, occasionally, systemic corticosteroids.

Kawasaki's disease is considered a polyarteritis nodosa variant because of the involvement of coronary arteries. Skin findings constitute several of the criteria for diagnosis. None of the findings is specific for Kawasaki's disease, but the constellation of findings establishes the diagnosis. Kawasaki's disease usually affects young children but has been reported in adults. Criteria for diagnosis are otherwise unexplained fever for at least 5 days and four of the following five findings: (1) bilateral nonexudative conjunctivitis; (2) injected pharynx, strawberry tongue, or injected or fissured lips; (3) erythema of palms or soles, hand and foot edema, and, in the convalescent phase, desquamation; (4) erythematous, polymorphous, generalized skin eruption; and (5) cervical lymphadenopathy. In addition, erythema of the perineal region is common and transverse lines across the fingernail beds have been noted in a few cases.

### Large Vessel Vasculitis

Skin findings of temporal arteritis (giant cell arteritis) consist mainly of palpable temporal arteries, skin tenderness in the area, and scalp nodules or ulcerations. Skin lesions in patients with Takayasu's arteritis may include Raynaud's phenomenon, livedo reticularis, ulcerated nodules, subcutaneous nodules, and pyoderma gangrenosum–like ulcers. Skin biopsy is generally not performed in these conditions.

## INFECTIONS

**KEY POINTS**

**Infections frequently occur on the skin and can mimic autoimmune skin diseases.**

**Skin biopsies can help confirm some types of skin infections, and some require a skin biopsy for culture to determine the organism and drug sensitivity.**

Patients with many infectious diseases present with both skin and rheumatologic findings.[69] This section will highlight a few examples.

### Lyme Borreliosis

*Borrelia burgdorferi*, the causative agent of Lyme disease in North America, is associated with erythema migrans (EM). In Europe the related genospecies *Borrelia afzelii* is associated with both EM and acrodermatitis chronica atrophicans (ACA), and several European studies have found compelling evidence for *B. afzelii* infection in patients with morphea. There has been no similar association of *Borrelia* with morphea in the United States.[70] Hematogenous dissemination from the initial skin site is believed to cause secondary skin lesions and extracutaneous manifestations, and only certain subtypes of *B. burgdorferi* are associated with dissemination.

EM is the first manifestation of Lyme disease in 60% to 80% of people and occurs at the site of the tick bite.[71] At the time of the skin lesion, which occurs within a few days to a month after the bite, the spirochetes enter the circulation and disseminate. The skin findings may be associated with fever, chills, fatigue, headache, neck stiffness, myalgias, arthralgias, conjunctivitis, erythematous throat, and regional or generalized lymphadenopathy. The lesions of EM begin as red macules that become papular and then expand into an erythematous, annular plaque (Figure 43-14). Two forms of EM exist. In one, there is an expanding red plaque with varying intensities of redness within the plaque. In the second, there is a target, with a central red plaque surrounded by normal-appearing skin, which in turn is surrounded by another band of erythema. They can enlarge rapidly, and multiple lesions resulting from hematogenous spread are seen 17% of the time. While the lesion enlarges, the central erythema can fade. The central portion of the lesion may be edematous, vesicular, urticarial, or crusted. Triangular and elongated oval lesions have been described, but circular lesions are most frequent. The most common locations are the inguina, axillae, abdomen, and behind the knees. EM lesions are usually asymptomatic but can be pruritic or painful. Untreated EM lesions resolve in a median of 28 days, with a range from 1 day to 14 months. Resolution is within a few days after treatment with antibiotics such as doxycycline or penicillin.

**Figure 43-14** Lyme disease with characteristic erythematous, annular plaques. *(Courtesy Dr. Joshua Levin, University of Pennsylvania Department of Dermatology, Philadelphia.)*

ACA is associated with late-stage Lyme disease. It occurs mainly in women between the ages of 40 and 70 years. The lesions begin on an extremity, usually the lower leg or foot as a bluish-red edematous plaque. Fibrous bands may develop, especially on the ulnar and tibial regions, and fibrous nodules may form near joints. Regional lymphadenopathy is often present. Over many years, the skin becomes atrophic.[72] *B. burgdorferi* has been isolated from the skin of patients with ACA.[73]

### Parvovirus

The skin findings of patients seen with parvovirus B19 include an erythematous "slapped cheeks" appearance; a lacy, reticulated proximal extremity rash; a febrile petechial eruption; and papular-purpuric gloves and socks syndrome (PPGSS). The infection is self-limited and generally resolves spontaneously within 1 to 2 weeks. Laboratory findings may include mild or severe leukopenia, transient neutropenia or relative neutrophilia, eosinophilia, and mild thrombocytopenia. Adults who are infected often contract the virus from infected children and commonly present with systemic disease, including arthropathy and a flu-like illness, and with additional skin lesions of periflexural pattern and purpura.[74]

### Atypical Infections: *Mycobacterium marinum*

Many types of mycobacteria, atypical mycobacteria, and deep fungal infections can affect skin and joints. *Mycobacterium marinum* is an example and can be acquired through exposure to fresh water, salt water, fish tanks, swimming pools, fish or aquatic exposures, timber cuts, or splinters. The incubation period is usually about 3 weeks, although much longer periods are possible. The disease often occurs after inoculation into abrasions or after penetrating injuries to the fingers and hands. This is an indolent disease, with nodules or ulcerated plaques, occasionally with extension to deep tissue. Common areas of involvement are the fingers, dorsum of the hands, and knees. The lesions can be localized or sporotrichoid (25%), with dissemination 2% of the time.

## PANNICULITIS

**KEY POINTS**

**There are many causes and types of panniculitis. Some are associated with systemic conditions and require a careful history and physical examination, along with a skin biopsy, to determine the cause.**

**Diseases such as amyloidosis and sarcoidosis can involve the skin and can be diagnosed with the help of a skin biopsy. A diagnosis of these diseases in the skin should prompt a search for systemic involvement. Treatment is determined by the cause of the disease and the organs involved.**

Panniculitis refers to a group of diseases that manifest as inflammation or alterations in the subcutaneous fat. The complexity of etiologies for even one form of panniculitis, such as erythema nodosum, the relative rarity of most forms of panniculitis, and the number of different panniculitides has slowed progress in elucidating pathogenesis. The etiologies for many panniculitides are still poorly understood.

Panniculitis may be primary without an identifiable cause, or secondary. Common secondary causes of panniculitis include infection, trauma, pancreatic disease, immunodeficiency states, malignancies, and connective tissue disease. Erythema nodosum remains the most common form of panniculitis, and although there is a long list of diseases and medications with which it is associated, it is frequently not associated with an identifiable underlying condition. Some underlying conditions associated with erythema nodosum include inflammatory bowel disease; sarcoidosis; malignancies such as leukemia and lymphoma; infections (bacteria, *Yersinia*, rickettsiae, chlamydial, spirochetal, and protozoal disease); pregnancy; drugs (sulfonamides and contraceptives); and autoimmune diseases such as Behçet's disease, Sjögren's syndrome, reactive arthritis, and SLE.[75]

Although the understanding of lobular panniculitis has expanded, cases that were lumped into the wastebasket diagnosis of "Weber-Christian" disease are now recognized to be clearly definable and separate entities, such as lupus panniculitis, cytophagic histiocytic panniculitis, subcutaneous panniculitis-like T cell lymphoma, $\alpha_1$-anti-trypsin deficiency, factitial panniculitis, traumatic panniculitis, calciphylaxis, and drug-induced.[76-78] Infections are recognized as a trigger of panniculitis, as exemplified by erythema nodosum caused by streptococcal infection; hepatitis B or C associated with polyarteritis nodosa; infectious panniculitides, often in immunocompromised hosts; and most recently, some cases of erythema induratum/nodular vasculitis associated with *Mycobacterium tuberculosis*. In addition, atypical infections can themselves cause lesions that resemble panniculitis.

An understanding of the heterogeneity of lymphomas that involve the fat is still evolving, but advances in differentiating various histologic and clinical outcomes are occurring.[79] Some patients thought to have lupus panniculitis on the basis of cytopenias and laboratory tests are actually diagnosed with subcutaneous lymphoma after careful review of their pathology.[79,80]

Patients with panniculitis frequently have erythematous tender nodules, and the clinical presentation frequently is not specific enough to allow for determination of the exact subtype of panniculitis without a biopsy. Patients with panniculitis can have associated symptoms such as low-grade fevers, fatigue, arthralgias, and myalgias.

An adequate skin biopsy, often involving an elliptical excision, is essential to properly diagnose the various entities that fall into the category of panniculitis (Table 43-1). Panniculitis is typically classified into four main subgroups: septal, lobular, mixed panniculitis, and panniculitis with vasculitis, and the exact nature of the cellular infiltrate also contributes to a proper diagnosis. There is no question that these overall categorizations help to narrow the differential in any given case, but at times, there are overlapping features or reaction patterns that do not allow for a specific diagnosis. Clinical-pathologic correlation is important, as emphasized by a published review that has an expanded and useful classification of panniculitis.[81]

Anecdotes exist about the efficacy of combination antimalarials, such as hydroxychloroquine and quinacrine, in

**TABLE 43-1** Classification of Panniculitis

| |
|---|
| **I. Without Prominent Vasculitis** |
| A. Septal inflammation |
| 1. Lymphocytic and mixed: erythema nodosum and variants |
| 2. Granulomatous: palisaded granulomatous diseases, sarcoidosis, subcutaneous infection: tuberculosis, syphilis |
| 3. Sclerotic: scleroderma, eosinophilic fasciitis, lipodermatosclerosis, toxins |
| B. Lobular inflammation |
| 1. Neutrophilic: infection, ruptured folliculitis and cysts, pancreatic fat necrosis |
| 2. Lymphocytic: lupus panniculitis, poststeroid panniculitis, lymphoma/leukemia |
| 3. Macrophagic: histiocytic cytophagic panniculitis |
| 4. Granulomatous: erythema induratum/nodular vasculitis, palisaded granulomatous diseases, sarcoidosis, Crohn's disease |
| 5. Mixed inflammation with many foam cells: $\alpha_1$-anti-trypsin deficiency, Weber-Christian disease, traumatic fat necrosis |
| 6. Eosinophilic: eosinophilic panniculitis, arthropod bites, parasites |
| 7. Enzymatic fat necrosis: pancreatic enzyme panniculitis |
| 8. Crystal deposits: sclerema neonatorum, subcutaneous fat necrosis of the newborn, gout, oxalosis |
| 9. Embryonic fat pattern: lipoatrophy, lipodystrophy |
| **II. With Prominent Vasculitis (Septal or Lobular)** |
| A. Neutrophilic: leukocytoclastic vasculitis, subcutaneous polyarteritis nodosa, thrombophlebitis, ENL |
| B. Lymphocytic: nodular vasculitis, perniosis, angiocentric lymphomas |
| C. Granulomatous: nodular vasculitis/erythema induratum, ENL, granulomatosis with polyangiitis, Churg-Strauss allergic granulomatosis |
| **III. Mixed Patterns** |

ENL, Erythema nodosum leprosum.

treating subcutaneous sarcoid, but no studies exist that support definitive recommendations. Reports on the use of newer therapies, such as mycophenolate mofetil and thalidomide to treat inflammatory causes of panniculitis, such as nodular panniculitis and erythema nodosum, are already in the literature, and indicate that these drugs will likely evolve to be useful for these conditions.[82,83] The effectiveness of these and more established drugs, such as NSAIDs, anti-malarials, and methotrexate, need to be studied, and outcomes will hopefully be more systematically evaluated.

## RELAPSING POLYCHONDRITIS

The diagnosis of relapsing polychondritis (RP) is based on the typical clinical manifestations, with auricular findings seen in 90% of patients. Nasal and respiratory tract chondritis can occur, along with nonerosive inflammatory arthritis, cardiac valvular insufficiency, vasculitis, eye, and audiovestibular involvement. The estimated prevalence of 3.5 per million makes controlled trials nearly impossible. The etiology is unknown, but the pathogenesis appears to be mediated by an immune reaction to type II collagen. Clinical skin manifestations include inflammation of the ear, with sparing of the earlobe. Diagnosis includes the presence of a positive serum antibody test to type II collagen and a wedge biopsy that shows cartilage necrosis and perichondral inflammation with lymphocytes and histiocytes. Involvement of other cartilage areas, including the upper airway, should be assessed. Glucocorticoids are the therapeutic choice for reducing the inflammatory process in patients with RP. For patients with sustained disease, many immunosuppressive drugs have been used as steroid-sparing agents. There have been reports of response to TNF inhibitors, rituximab, tocilizumab, and abatacept in patients otherwise refractory to therapy.[84]

## INFILTRATIVE DISEASES

### Amyloid

Type AL amyloidosis (primary amyloidosis) is rare, with an incidence of less than 1 per 100,000 individuals. Skin lesions may occur in as many as 40% of these patients. Skin lesions can be an early sign of the disease and may include purpura, petechiae, and ecchymoses caused by infiltration of blood vessels by amyloid. Other skin findings include alopecia, plaques, and nodules, often found on flexor surfaces, the face, or the buccal mucosa. Bullae and nail dystrophy are occasionally seen. Diagnosis is confirmed by biopsy of lesional or nonlesional skin, along with urine and serum for immunoelectrophoresis to confirm the presence of a circulating monoclonal protein. Skin biopsy shows Congo-red positive, homogeneous, hyaline, fibrillary deposits. Treatment includes autologous stem cell transplantation, with approximately 50% of patients achieving prolonged remission with such therapy. Other effective therapies include the combination of melphalan with high-dose dexamethasone, thalidomide, and recent stem cell transplant in conjunction with melphalan.[85,86] The prognosis depends on the stage at the time of diagnosis, which emphasizes the importance of recognizing the disease.

### Sarcoidosis

Cutaneous involvement occurs in 20% to 25% of sarcoidosis cases and is most likely to be seen early in the disease. Cutaneous lesions can be classified as nonspecific, typically erythema nodosum, and specific or granulomatous. Erythema nodosum occurs frequently as part of Lofgren's syndrome, with bilateral hilar lymphadenopathy and acute iridocyclitis. This variant has a good prognosis and resolves in 80% of patients within 2 years. The skin lesions of sarcoidosis generally have no prognostic significance or correlation with disease activity. Skin involvement has no effect on the course of the disease, and the number of skin lesions does not correlate with systemic disease. Skin plaques tend to be more persistent and commonly associated with chronic forms of the disease. Lupus pernio (Figure 43-15), with violaceous plaques on the nose, ears, cheeks, lips, and fingers, is often seen in long-standing sarcoidosis and is associated with upper airway involvement and pulmonary fibrosis.[87] Other forms of cutaneous sarcoidosis include papules, follicular papules, subcutaneous nodules, ulcerative lesions, alopecia, and ichthyosis. Cutaneous sarcoid can arise in scars. Because of the many types of presentation, diagnosis can be challenging, and a skin biopsy is necessary to confirm the clinical suspicion. Mimickers of papules include xanthelasma, rosacea, trichoepithelioma, syphilis, LE, and granuloma annulare. Plaques can resemble lupus vulgaris, necrobiosis lipoidica, morphea, leprosy, *Leishmania*, or lupus erythematosus. Nodules can

**Figure 43-15** Sarcoidosis with "apple-jelly" plaques on the face and lupus pernio, or nasal rim lesions.

resemble lymphoma or other types of panniculitis. Treatment of cutaneous sarcoidosis depends on the degree of systemic involvement. Clearly, patients who need prednisone for systemic disease often experience improvement of their cutaneous sarcoid. Patients with isolated skin disease or systemic disease that does not require aggressive therapy can benefit from topical or intralesional corticosteroids, topical tacrolimus, minocycline, hydroxychloroquine, combination anti-malarials with hydroxychloroquine and quinacrine, or chloroquine. If anti-malarials are not adequate, then methotrexate or oral retinoids may be used. There have been case reports and small case series of successful therapy with thalidomide and TNF inhibitors, as well as laser remodeling of lupus pernio. There is some concern that TNF inhibitors and IFN-α therapy may induce sarcoidosis.

## MISCELLANEOUS SKIN DISEASES AND ARTHRITIS

**KEY POINTS**

**There are a number of autoinflammatory diseases, including Behçet's disease, familial Mediterranean fever, and cryopyrin-associated periodic syndromes that involve mutations of the inflammasome and can be treated with inhibitors of upregulated cytokines.**

### Behçet's Disease

Behçet's disease is most prevalent in the Middle East and the Far East. Human leukocyte antigen (HLA)-B5 and HLA-B51 genes are important in the pathogenesis of the disease. The criteria for Behçet's disease (BD) include recurrent oral and genital ulcers, eye lesions (uveitis or retinal vasculitis), characteristic skin lesions, and a positive pathergy test.[88] The pathergy test involves use of a sterile needle to prick the forearm. The results are positive when the puncture causes an aseptic erythematous nodule or pustule that is more than 2 mm in diameter at 24 to 48 hours. A diagnosis is made if patients have recurrent oral ulceration plus at least two of the other findings without other clinical explanations. Skin lesions include erythema nodosum, pseudofolliculitis, or papulopustular lesions or acneiform nodules in postadolescents. Oral ulcers are painful and occur on the gingiva, tongue, and buccal and labial mucosa. Genital ulcers, usually larger and deeper than oral ulcers, are typically on the scrotum and penis in men and the vulva in women. Venous involvement, including superficial thrombophlebitis and deep venous thrombosis, can occur. On skin biopsy, small vessel vasculitis is common. Ulcer treatment includes topical corticosteroids, colchicine, and thalidomide, and there are some reports of biologics, including inhibitors of IL-1, IL-6, IL-12/23, and TNF, being helpful.[89] Systemic corticosteroids are prescribed for unresponsive erythema nodosum.

### Familial Mediterranean Fever

Familial Mediterranean fever (FMF) is an autosomal recessive disease that tends to affect certain ethnic groups, including Sephardic Jews, Arabs, Armenians, and Turks. There is a mutation on the short arm of chromosome 16, and the mutant protein pyrin likely plays an inhibitory role in the control of inflammation.[90,91] It is characterized by recurrent, self-limited attacks of peritonitis, pleuritis, and synovitis. Erysipelas-like erythema (ELE) is the pathognomonic skin manifestation. This is characterized by tender erythematous, well-demarcated plaques, usually located on the lower legs.[92] They may be triggered by physical effort and subside spontaneously within 48 to 72 hours of bed rest. Fever and leukocytosis may accompany this condition. Other associated skin findings include Henoch-Schönlein purpura; nonspecific purpura; erythema of the face, trunk, or palm; angioneurotic edema; Raynaud's phenomenon; pyoderma; and subcutaneous nodules. Secondary generalized amyloidosis may lead to chronic renal failure and death if not recognized. Skin biopsy shows edema of the superficial dermis and sparse perivascular infiltrate composed of a few lymphocytes, neutrophils, and nuclear dust, without vasculitis. Direct immunofluorescence shows deposits of C3 in the wall of small superficial vessels. Early treatment with colchicine, which prevents or diminishes the frequency and severity of the inflammatory episodes, can be beneficial. Refractory patients may benefit from IL-1 blockade.

### Multicentric Reticulohistiocytosis

Multicentric reticulohistiocytosis (MRH) is a rare condition of unknown etiology that most frequently occurs in Caucasian women in their fifth and sixth decades. There is destructive symmetric arthritis, with arthritis mutilans developing in approximately 45% of cases, associated with cutaneous papulonodular lesions. Skin findings include cutaneous red-to-brown papules or nodules, typically on the face, dorsum of the fingers, and over the proximal and distal interphalangeal joints, but they can be in a more generalized distribution. A rarer presentation includes photodistributed

erythema, often with targeting over joints that masquerades as DM.[93] Diagnosis is made by skin biopsy, which shows infiltration of histiocytes and multinucleated giant cells. These changes can be seen in a variety of tissues, including the heart, lungs, skeletal muscle, and gastrointestinal tract. The differential diagnosis of skin disease includes other infiltrative processes, such as sarcoidosis and even leprosy. Treatment recommendations, based on mostly small case reports, include glucocorticoids and methotrexate, cyclophosphamide, and finally chlorambucil if the condition is unresponsive.[94] Cyclosporine, TNF inhibitors, and bisphosphonates have also been used with reported benefit.[95] In approximately one-third of patients, MRH may precede or follow an underlying malignancy. Reported associated malignancies include breast, cervix, colon, stomach, lung, larynx, ovary, lymphoma, leukemia, sarcoma, melanoma, mesothelioma, and metastatic cancer of unknown primary.

## Cryopyrin-Associated Periodic Syndromes

Cryopyrin-associated periodic syndromes (CAPS) are inherited autoinflammatory conditions characterized by recurrent bouts of systemic inflammation related to inappropriate activation of the innate immune system. The syndrome encompasses a continuum of three diseases. The mildest is familial cold autoinflammatory syndrome (FCAS). Patients with FCAS present with recurrent, cold-induced episodes of fever, urticaria-like rash, arthralgia, and conjunctivitis. Patients with Muckle-Wells syndrome (MWS) have an intermediate phenotype. In MWS, the disease tends to be chronic, with fever, rash, and arthritis or arthralgia; sensorineural hearing loss; and AA amyloidosis in adulthood. The most severe (neonatal-onset multisystem inflammatory disease [NOMID]), also referred to as *chronic infantile neurologic cutaneous articular* [CINCA] syndrome). In CINCA/NOMID, fever is rare. Patients present with an early onset, intermittent, urticaria-like rash, and neurosensory involvement. Hypertrophic arthropathy with contractures and bone deformity can occur in severely affected patients with CINCA/NOMID. CAPS are caused by dominantly inherited, or de novo gain-of-function mutations within the *NLRP3* gene. Somatic mutations have been recently described in CINCA/NOMID germline-mutation–negative patients. *NLRP3* encodes cryopyrin, a cytosolic protein complex that controls activation of caspase-1, which then activates IL-1β. Mutations in *NLRP3* are associated with overactivation of the inflammasome and thus overexpression of IL-1β. Inhibition of IL-1β can dramatically improve all the clinical manifestations related to this type of inflammation.[96] Isolated reports also suggest that TNF inhibitors and thalidomide can be beneficial therapeutically in these patients.

CHAPTER 44

# The Eye and Rheumatic Diseases

James T. Rosenbaum

**KEY POINTS**

- Symptoms of uveitis vary widely based on the location of the inflammation within the eye and the suddenness of onset.
- Ankylosing spondylitis is the systemic rheumatic disease most often associated with uveitis in North America and Europe.
- During a lifetime, acute anterior uveitis develops in about 40% of patients with ankylosing spondylitis.
- The uveitis associated with HLA-B27 tends to be unilateral, recurrent, and sudden in onset. Recurrences sometimes affect the opposite eye.
- Sarcoidosis frequently manifests as uveitis.
- Most patients with retinal vasculitis do not have systemic vasculitis.
- Many patients with scleritis have a systemic disease, such as rheumatoid arthritis.
- Anti-neutrophilic cytoplasmic antibody testing helps identify a subset of patients with severe scleritis.
- Granulomatosis with polyangiitis is the rheumatic disease that most frequently involves the orbit.
- Anterior ischemic optic neuropathy is the most common ocular manifestation of giant cell arteritis.
- Most patients with visual loss resulting from optic nerve ischemia do not have arteritis.

Virtually all of the systemic inflammatory diseases that require rheumatologic care tend to affect the eye or its surrounding structures. Table 44-1 presents the prototypic ocular manifestations of rheumatoid arthritis, systemic lupus erythematosus, Sjögren's syndrome, spondyloarthropathies, vasculitides including granulomatosis with polyangiitis and giant cell arteritis (also known as temporal arteritis), scleroderma, Behçet's disease, relapsing polychondritis, and dermatomyositis. Each of these diseases is addressed elsewhere in this text. This chapter focuses on specific ocular structures—the uvea, cornea, orbit, and optic nerve—and illustrates how inflammation of each might relate to an autoimmune or inflammatory process.

## OCULAR ANATOMY AND PHYSIOLOGY

A diagram of the eye is shown in Figure 44-1. The eye is a tiny but elegantly complex structure. The anterior segment of the eye includes the cornea, which is avascular and transparent when healthy. The lens also is an avascular structure. The anterior chamber is filled with aqueous humor, which has homology to cerebrospinal fluid. When the blood-aqueous barrier is intact, the aqueous humor contains no leukocytes and very little protein. The blood-aqueous barrier, which resembles the blood-synovial barrier, is disrupted in anterior uveitis. In this case, a routine, noninvasive biomicroscopic or slit lamp examination would reveal leukocytes and increased protein in the anterior chamber. An ophthalmologist has the opportunity to observe two universal hallmarks of inflammation noninvasively.

The term *uvea* derives from the Latin word for "grape." The anterior uvea includes the iris and the ciliary body. The aqueous humor is synthesized by the ciliary body. The posterior portion of the uvea is the choroid, which is a highly vascular tissue just posterior to the retina. Any portion of the uveal tract could become inflamed, and adjacent tissue also is frequently inflamed. Anatomic subsets of uveitis include anterior uveitis, which consists of iritis or iridocyclitis (ciliary body inflammation); intermediate uveitis, in which leukocytes are present within the vitreous humor; and posterior uveitis, in which the choroid and the retina are inflamed. *Panuveitis* occurs when all portions of the uveal tract are inflamed. An attempt has been made to standardize the nomenclature used to describe uveitis by the Standardization of Uveitis Nomenclature Working Group,[1] although ambiguities persist because not all ophthalmologists follow these definitions as yet.

Signs and symptoms of uveitis depend on the portion of the uveal tract that is affected. An anterior uveitis, especially if it begins suddenly, is associated with redness, pain, and photophobia. Visual loss varies and often is due to macular edema if present (Figures 44-2 and 44-3). An intermediate uveitis usually causes floaters as a result of leukocytes that enter the visual axis, although most floaters are due to aging or other changes within the vitreous humor. Posterior uveitis by itself does not usually produce pain or redness. Visual loss depends on the location and extent of the inflammatory process.

The outer tunic of the eye is known as the *sclera*. At the front of the eye, the sclera meets the cornea at a tissue known as the *limbus*. The most interior layer of the eye is an extension of the brain that responds to visual signals, the *retina*. The eye shares some common features with joints, including the presence of hyaluronic acid primarily in the vitreous humor and the presence of type II collagen, although ocular inflammation is not a reported accompaniment of collagen-induced arthritis. Aggrecan is a proteoglycan present both in the eye and in joints. An autoimmune response to aggrecan in BALB/c mice can produce both arthritis and uveitis.[2]

**TABLE 44-1** Most Characteristic Ocular Findings of Selected Rheumatic Diseases

| Disease | Most Characteristic Ocular Findings |
|---|---|
| Rheumatoid arthritis | Sicca<br>Scleritis |
| Systemic lupus erythematosus | Sicca<br>Cotton-wool spots |
| Sjögren's syndrome | Sicca |
| Spondyloarthritis | Acute anterior uveitis |
| Granulomatosis with polyangiitis | Scleritis<br>Orbital inflammation |
| Giant cell arteritis | Anterior ischemic optic neuropathy |
| Scleroderma | Sicca |
| Behçet's disease | Uveitis, retinal arteritis |
| Relapsing polychondritis | Scleritis, episcleritis, uveitis |
| Dermatomyositis | Heliotrope eyelids |

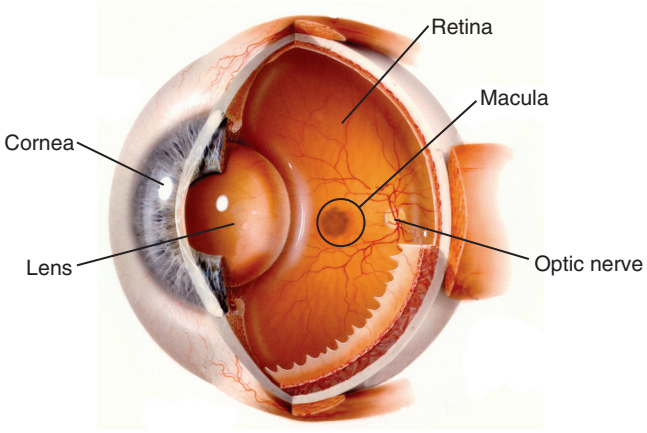

**Figure 44-1** Diagram of the eye.

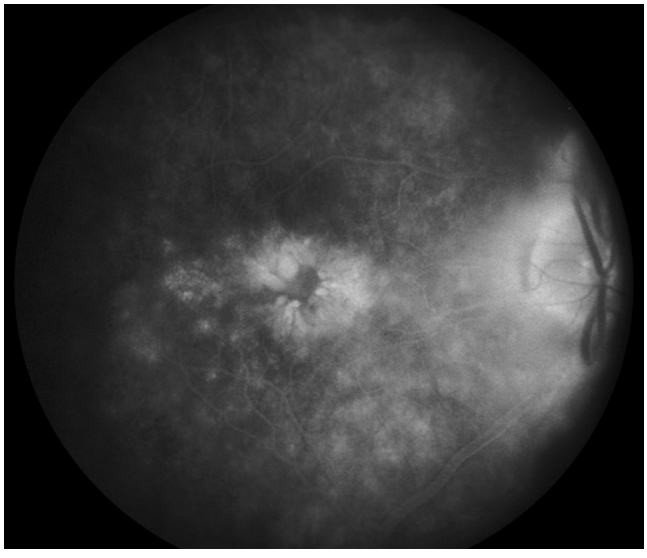

**Figure 44-2** A fluorescein angiogram. The normal macula is avascular and does not stain with fluorescein dye. This patient has macular edema, as indicated by the donut-shaped pattern of dye in the center of the photo. The optic nerve is at the 3-o'clock position in the photo. Macular edema can complicate uveitis, even anterior uveitis.

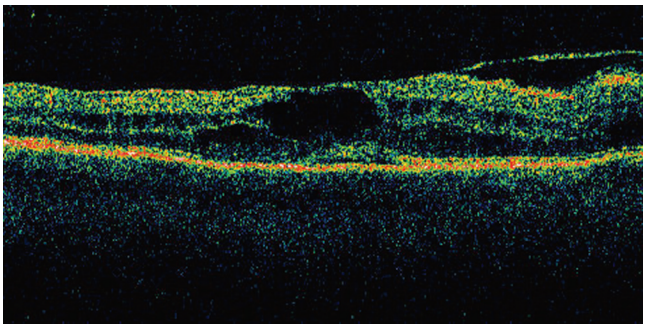

**Figure 44-3** Optical coherence tomography produces precise imaging of the retinal structure. The ovoid black hole in the center of the image is due to macular edema, a major cause of visual loss in patients with uveitis.

Because uveitis and arthritis co-exist in multiple diseases, it is logical to seek the mechanism for this co-existence. It is likely that the mechanism for one disease, such as ankylosing spondylitis, might differ from the mechanism that explains the co-existence of eye and joint disease in Blau syndrome or in juvenile idiopathic arthritis (JIA). In a disease such as reactive arthritis, bacterial products might be trapped in synovium, where they become the target of an immune response. A similar pathogenesis in the iris is difficult to prove because of a relative inability to obtain a biopsy specimen of uveal tissue while it is inflamed, but many microbial products are inflammatory within the eye.[3] Because the eye and joints share specific antigens such as aggrecan, an autoimmune response could also account for the simultaneous inflammation of uvea and joints.

## OCULAR IMMUNE RESPONSE

The eye generally is regarded as an immune privileged site.[4] From a teleologic perspective, many scientists believe that the eye has developed mechanisms to avoid becoming inflamed because of the consequences that inflammation has for visual acuity. Similar to the brain, the internal portion of the eye has no lymphatics, although the conjunctiva on the ocular surface has lymphatic drainage. Portions of the eye—the cornea and the lens—are avascular. The aqueous humor contains several factors that are known to be immunosuppressive, including transforming growth factor-β and α-melanocyte–stimulating hormone. Several tissues within the eye express ligands that promote apoptosis, including tumor necrosis factor (TNF)–related apoptosis-inducing ligand (TRAIL) and Fas ligand. If a soluble antigen is injected into the anterior chamber, a cellular immune response is suppressed. This phenomenon is known as anterior chamber–associated immune deviation (ACAID). These factors are important to consider in the effort to understand why the eye sometimes is targeted as part of an immune or inflammatory disease.

## UVEITIS

Rheumatologists may be consulted to identify a systemic disease in a patient with uveitis, and a rheumatologist often is asked to assist in the management of immunosuppression in select patients with uveitis. In some referral practices for patients with uveitis, 40% of patients might have an

associated systemic illness. Table 44-2 lists the differential diagnoses of uveitis. The immunologic diseases most likely to be associated with uveitis are listed in Table 44-3.

The most common systemic illness associated with uveitis in most North American practices is ankylosing spondylitis. From an epidemiologic perspective, anterior uveitis is more common than posterior or intermediate uveitis.[5]

About 50% of persons with anterior uveitis are positive for human leukocyte antigen (HLA)-B27.[6] The uveitis associated with HLA-B27 is almost always unilateral, recurrent, of relatively short duration (<3 months per attack), resolves completely between attacks, and is associated with reduced intraocular pressure (in contrast to herpes simplex, which can cause recurrent anterior uveitis associated with increased intraocular pressure).[7] Hypopyon or pus in the anterior chamber sometimes is present in patients with HLA-B27–associated uveitis (Figure 44-4). Recurrent episodes can affect the contralateral eye, but simultaneous bilateral involvement is rare. Many studies have tried to address the question of how frequently a patient with HLA-B27–associated anterior uveitis has an associated spondyloarthropathy. A wide range of answers have been suggested, and the percentage depends on the definition of spondyloarthropathy, but one reasonable estimate is that 80% of HLA-B27$^+$ patients with acute anterior, unilateral uveitis have associated spondyloarthropathy.[6]

**TABLE 44-2** Differential Diagnosis of Uveitis

| |
|---|
| Infections—toxoplasmosis, syphilis, herpes simplex, herpes zoster, and cytomegalovirus |
| Systemic, immune-mediated diseases |
| Masquerade syndromes, such as lymphoma |
| Syndromes confined to the eye, such as pars planitis, birdshot chorioretinopathy, and serpiginous choroiditis |

**TABLE 44-3** Immune-Mediated Diseases Most Often Associated with Uveitis

| |
|---|
| Ankylosing spondylitis |
| Behçet's disease |
| Drug/hypersensitivity reactions |
| Familial granulomatous synovitis |
| Inflammatory bowel disease |
| Interstitial nephritis |
| Juvenile idiopathic arthritis |
| Multiple sclerosis |
| Neonatal-onset multisystem inflammatory disease |
| Psoriatic arthritis |
| Reactive arthritis |
| Sarcoidosis |
| Sweet's syndrome |
| Systemic lupus erythematosus |
| Vasculitis, especially Cogan's syndrome and Kawasaki's disease |
| Vogt-Koyanagi-Harada syndrome |

The uveitis associated with reactive arthritis is indistinguishable from the uveitis associated with ankylosing spondylitis. In either of these entities, acute anterior uveitis develops in about 40% of patients during a lifetime. Although conjunctivitis is part of the classic triad of reactive arthritis (in association with arthritis and nongonococcal urethritis), conjunctivitis is uncommon. A genome-wide screen for susceptibility genes for acute anterior uveitis identified loci that predispose to ankylosing spondylitis and loci that seem to be unassociated with susceptibility to ankylosing spondylitis.[8]

Uveitis develops in approximately 5% of persons with inflammatory bowel disease and 7% of persons with psoriatic arthritis. Although some of these persons have disease that is unilateral, anterior, and recurrent, many have disease that is bilateral, chronic in duration, and posterior to the lens.[9,10] About half of all patients with Crohn's disease or psoriatic arthritis and uveitis are positive for HLA-B27.

Sarcoidosis is the second most common systemic disease associated with uveitis, at least in North America, and in some geographic areas it might be more common than spondyloarthritis. Sarcoidosis is promiscuous within the eye, meaning that it can affect a wide range of structures, including the orbit, lacrimal gland, anterior uvea, vitreous humor, choroid, retina, or optic nerve. Ocular inflammation with sarcoidosis frequently is termed *granulomatous* because large collections of cells deposit on the back of the cornea (Figure 44-5). A retinal vasculitis can be a prominent feature of sarcoidosis, even though systemic vasculitis is not a typical feature of the disease; this phenomenon results in part from the manner in which vasculitis is diagnosed in the retina.

Histologic evidence of vessel wall destruction is rarely obtained because of the morbidity associated with a retinal biopsy. Instead, retinal vasculitis is diagnosed on the basis of perivascular sheathing along a vessel as seen on funduscopic examination (Figure 44-6), intraretinal hemorrhages that must be secondary to vascular injury, and fluorescein angiography indicating increased vascular permeability.[11] Most rheumatologists find the term *retinal vasculitis* misleading because the classic systemic vasculitides, such as polyarteritis nodosa and granulomatosis with polyangiitis, are rarely associated with retinal vasculitis.[12]

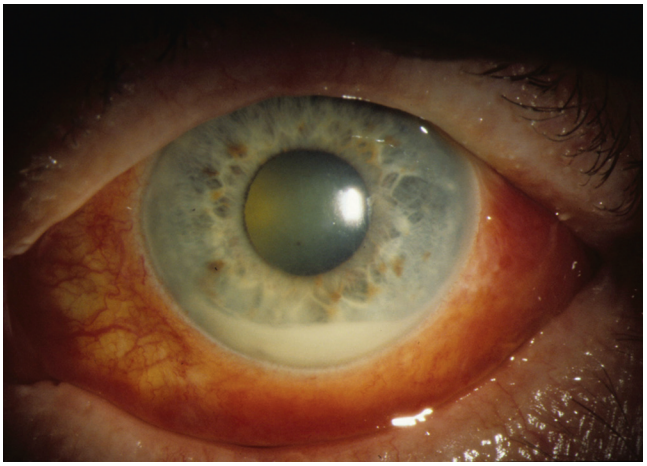

**Figure 44-4** The creamy material at the bottom of the pupil is an accumulation of leukocytes, also known as a hypopyon.

Initially, sarcoidosis frequently manifests as an ocular problem.[13] An ocular symptom is the initial manifestation almost as frequently as a pulmonary symptom. Sarcoidosis frequently involves the conjunctiva, which is an accessible tissue for biopsy confirmation of the diagnosis. In most series of patients with uveitis, about 30% of patients have uveitis that defies placement within a diagnostic category.[14] Many of these patients may have sarcoidosis that is difficult to find outside the eye. The sensitivity and specificity of studies such as a serum angiotensin-converting enzyme level or gallium scan for sarcoid that is primarily ocular are unknown. I consider obtaining a chest computed tomography (CT) scan to look for symmetric hilar adenopathy in any patient who has uveitis of unknown origin.[15] The therapeutic implications of the result of the scan must be balanced against the cost and potential harm from radiation exposure.

JIA comprises several different diseases. Patients with juvenile ankylosing spondylitis resemble their adult counterparts in that a sudden-onset, unilateral anterior uveitis can develop. The subset of JIA that is most classically associated with uveitis tends to be female, with onset of arthritis between the ages of 2 and 8 years.[16] The joint disease is pauciarticular, and most patients are positive for antinuclear antibodies. The uveitis tends to have an insidious onset, such that pain and redness are almost always absent. Joint disease can be minimal as well, and some patients are not diagnosed until a visual screening examination is performed when starting school. The eye disease usually is bilateral and very persistent, although remissions have been well described. Band keratopathy, which is the deposition of calcium superficially in the cornea, is a well-known and frequent complication of this form of uveitis (Figure 44-7). Patients also may experience glaucoma and posterior *synechiae*, a term that describes adhesions of the iris to the lens.

Other forms of uveitis associated with joint disease include Behçet's disease, relapsing polychondritis, and vasculitis such as Cogan's syndrome and Kawasaki's disease. In Behçet's disease, uveitis is often the symptom that "drives" the therapy—that is, it is often the manifestation that most often requires systemic immunotherapy.[17] Eye inflammation usually is bilateral and recurrent. In contrast to the recurrences typical of ankylosing spondylitis, recurrences of uveitis with Behçet's disease, usually do not have complete resolution between attacks. A hallmark of Behçet's disease–associated uveitis is a retinal vasculitis. Retinal arteries are especially prone to be affected. The visual prognosis with Behçet's disease can be grim, and blindness is a frequent concomitant of untreated ocular disease.

Relapsing polychondritis can have an impact on almost any portion of the eye, including the episclera, sclera, and uveal tract.[18] Ocular inflammation is common.

Cogan's syndrome is classically defined as sensorineural hearing loss with corneal disease, especially interstitial keratitis. This definition usually is broadened to include any ocular inflammatory process, such as uveitis or scleritis. Although uveitis can occur with polyarteritis or granulomatosis can occur with polyangiitis, scleral disease is typical. In contrast, anterior uveitis in association with conjunctivitis is present in most patients with Kawasaki's disease.

Uveitis and arthritis occasionally can result from an infection such as Whipple's disease or Lyme disease. Uveal involvement with Lyme disease has been described but is extremely rare.

Some autoinflammatory diseases are associated with uveitis. Autoinflammatory diseases are characterized by

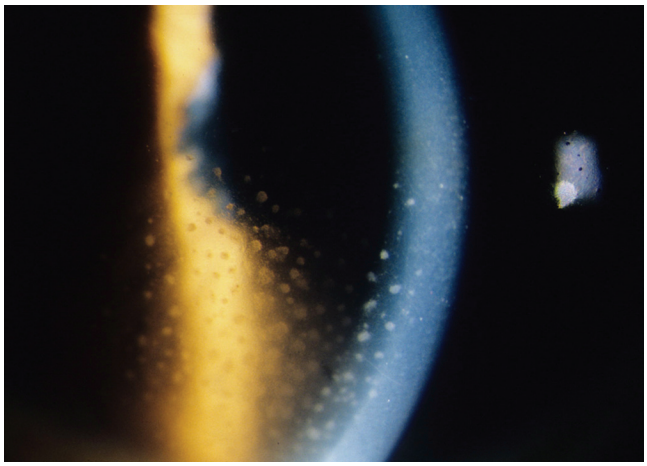

**Figure 44-5** Keratic precipitates. The white dots result from concretions of cells depositing against the corneal endothelium. These keratic precipitates are large and usually are described as granulomatous even though a granuloma is not present histologically.

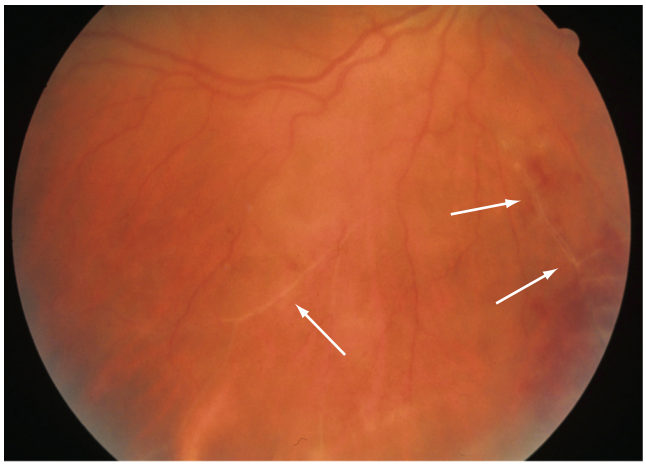

**Figure 44-6** Retinal vasculitis. *Arrows* indicate areas of vascular sheathing or occlusion.

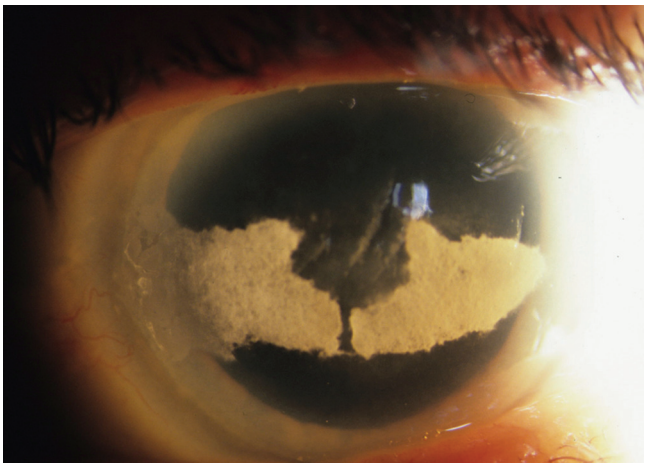

**Figure 44-7** Band keratopathy is illustrated by calcific patches stretching across the cornea.

widespread inflammation in the absence of detectable autoantibodies. Many autoinflammatory syndromes respond dramatically to inhibition of interleukin (IL)-1. Blau syndrome, which also is known as *familial granulomatous synovitis*, results from a single base change in the nucleotide-binding domain of the *NOD2* gene, which used to be known as *CARD15* or *NLRC2*.[19] Polymorphisms elsewhere in this same gene predispose to Crohn's disease. Blau syndrome is characterized by childhood onset of uveitis, arthritis, and dermatitis. Inflammation in additional organ systems also has been described. The disease is autosomal dominant. The histopathology of affected skin or joint can show noncaseating granuloma, as in sarcoidosis. Lung involvement has not been described in Blau syndrome, however. Gene sequencing has shown that many patients thought to have so-called early-onset sarcoidosis actually have new mutations in the *NOD2* gene.[20]

Neonatal-onset multisystem inflammatory disease (NOMID), which also is known as *chronic infantile neurologic cutaneous articular syndrome* (CINCA), is an autosomal dominant autoinflammatory syndrome. Ocular involvement in NOMID is more variable than in Blau syndrome. Characteristic findings include papilledema and uveitis.[21]

Treatment of uveitis depends on multiple factors, such as severity, location within the eye, patient preference, and the specific diagnosis (e.g., Behçet's disease might be especially responsive to infliximab[22] or interferon alfa[23]). For noninfectious causes of uveitis that involve the anterior portion of the eye, treatment usually begins with topical corticosteroids and often dilating drops to prevent posterior synechiae and to relieve spasm of the ciliary muscle. Periocular or intraocular corticosteroid injections, usually with triamcinolone, are given for inflammation posterior to the lens that is not responding to topical medication. Local corticosteroids can increase intraocular pressure, induce cataracts, interfere with the response to infection, and delay wound healing. A long-lasting corticosteroid implant containing fluocinolone has been approved by the U.S. Food and Drug Administration.[24] A cataract develops in all patients who elect to receive this type of therapy if the lens has not already been surgically removed, and glaucoma develops in most patients, with many persons requiring surgery to control the intraocular pressure. Intravitreal corticosteroid therapy can also be given in the form of dexamethasone in a slow-release formulation or as triamcinolone.

Systemic immunosuppressive therapy generally is reserved for patients with active, noninfectious causes of inflammation. For systemic immunosuppression to be indicated, the inflammation usually is bilateral and severe enough to interfere with activities of daily living. A variety of immunomodulatory medications have been tried to treat intraocular inflammation,[25] including azathioprine, chlorambucil, cyclophosphamide, cyclosporine, daclizumab, infliximab, methotrexate, mycophenolate mofetil, and tacrolimus. The optimal choice depends on many factors, not the least of which is the empiric result of any therapeutic approach. Maintaining a treatment for uveitis usually requires some efficacy in association with good tolerability. In this regard, at least one study found methotrexate to be superior to other anti-metabolites.[26] Because of the range of diseases being treated and the range of clinical response, room for all of these options exist in the therapeutic armamentarium of a uveitis clinic.

The optimal therapy for uveitis presumably depends on the underlying cause of the uveitis. The approach to uveitis in association with JIA should differ from the approach to uveitis resulting from Vogt-Koyanagi-Harada syndrome. However, the relative rarity of uveitis is such that few studies have been performed on specific forms of uveitis. For JIA-associated uveitis, many clinicians follow the algorithm of using topical therapy with prednisolone acetate initially and adding methotrexate if the inflammation is not controlled by drops used up to three times per day. If methotrexate does not help gain control of the inflammation, a monoclonal antibody to TNF is generally added to the regimen.

Biologic therapies increasingly are being used to treat patients with uveitis when the disease has proved refractory to other forms of immunomodulatory therapy. Infliximab is especially useful in the treatment of Behçet's disease.[22] One prospective study that assessed infliximab for a variety of forms of uveitis concluded that the drug was often effective but that it was also surprisingly toxic.[27] Consequently, the role of biologic therapies in most specific forms of uveitis is inadequately studied.[28]

In one review, a group of experts summarized the role of biologics in the therapy of various forms of uveitis.[29] A variety of investigational approaches for uveitis were being investigated at the time, including a monoclonal antibody to IL-17, a monoclonal antibody to IL-1β, and the intravitreal injection of rapamycin.

## SCLERITIS AND CORNEAL MELT

Many diseases cause a red eye, including conjunctivitis, keratitis, iritis, acute closed-angle glaucoma, episcleritis, and scleritis. Conjunctivitis is compared with episcleritis and scleritis in Table 44-4. A rheumatologist should refer patients with red eyes to an ophthalmologist if the problem is associated with pain, photophobia, and a change in visual acuity. Patients with persistent redness should also be referred.

**TABLE 44-4** Some Causes of Red Eyes: A Comparison

| | Conjunctivitis | Episcleritis | Scleritis |
|---|---|---|---|
| Discomfort | Scratchy | Scratchy | Pain |
| Redness | Diffuse, includes palpebral conjunctivae of lids | Diffuse or a sector, spares palpebral conjunctivae | Diffuse or a sector, spares palpebral conjunctivae |
| Causes | Allergy, viral, chemical irritant | Usually idiopathic but presumed immune response | Usually idiopathic but presumed immune response; can be an infection |
| Relation to systemic disease | Rare | Rare | Common (approximately 40%) |

Scleritis often is divided into five categories: diffuse anterior, nodular, necrotizing, scleromalacia perforans, and posterior (Figure 44-8). Each of the first three categories results in a red, painful eye. Pain is more variable in scleromalacia perforans, in which a nodule pathologically similar to a rheumatoid nodule forms in the sclera (Figure 44-9). Pain also varies with posterior scleritis, and because the sclera extends back to the optic nerve, posterior scleritis can occur in a localized fashion that does not lead to a red eye. Because of the risk of perforation, the sclera is not normally biopsied, but biopsy studies have shown that scleritis is often a granulomatous inflammation of scleral tissue.[30]

Patients with scleritis can experience complications within the eye, including uveitis, glaucoma, optic nerve edema, and retinal or choroidal distortion. A corneal melt or peripheral thinning of the cornea sometimes develops in persons with severe scleritis and represents a potentially blinding complication of the disease (Figure 44-10).

About 50% of patients with scleritis have an associated systemic illness.[31] The most common of such illnesses are limited granulomatosis with polyangiitis and rheumatoid arthritis. Generally, the associated rheumatoid arthritis is long standing and seropositive. Patients may have associated nodules, vasculitis, or pleuropericarditis. They have a shortened life expectancy compared with other patients with rheumatoid arthritis.[32] It is unusual for scleritis to be an initial manifestation of rheumatoid arthritis.

Granulomatosis with polyangiitis is commonly associated with scleritis. In contrast to rheumatoid arthritis, scleritis can be the initial manifestation of granulomatosis with polyangiitis. Obtaining anti-neutrophilic cytoplasmic antibody serology for any patient who presents with scleritis without an obvious systemic disease association is appropriate. Other systemic associations with scleritis include inflammatory bowel disease, relapsing polychondritis, other vasculitides such as giant cell arteritis, and ankylosing spondylitis. Infections are a rare but possible cause of scleritis. Tophaceous gout also has been reported as an unusual cause of scleritis.

Scleritis tends to be a painful and persistent disease that often lasts for years. In contrast, episcleritis involves more superficial tissue and is usually transient. Episcleritis may be a feature of rheumatoid arthritis, although many patients with episcleritis may not have any associated systemic illness. Complications within the eye, such as glaucoma or uveitis, are absent. Mild discomfort, rather than frank pain, is the usual presenting symptom. In contrast to scleritis, patients with episcleritis have vessels that constrict completely after 2.5% phenylephrine is placed on the surface of the eye.

Some patients with scleritis, especially those who do not have an associated systemic illness, are treated adequately with an oral nonsteroidal anti-inflammatory drug. Some experts treat scleritis with locally injected corticosteroids, but this approach should be avoided if the sclera is thin (a sign of necrotizing disease). In addition, corticosteroids have the theoretical risk of promoting thinning. The usual option for patients who do not respond to nonsteroidal anti-inflammatory drugs is oral prednisone. Some patients can be effectively treated with low doses of prednisone, but many patients require the addition of an antimetabolite as a steroid-sparing drug. Scleritis usually responds to treatment of the underlying disease if an associated disease is present. Thus control of rheumatoid arthritis or

**Figure 44-8** A scleral nodule. Active scleritis is present superior to the limbus. In this patient, scleritis has taken on a nodular configuration.

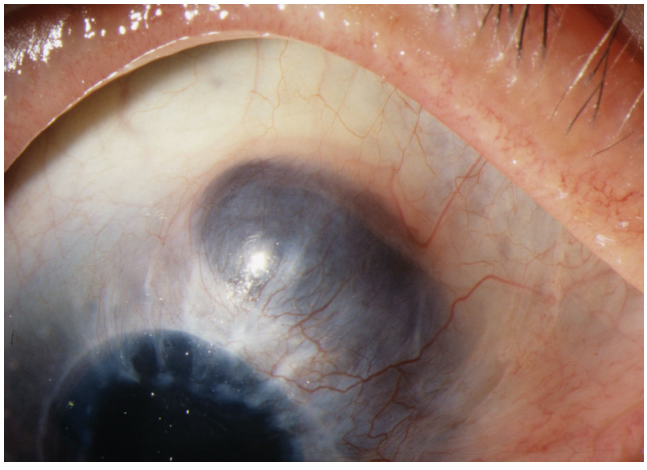

**Figure 44-9** Scleromalacia has resulted in ulceration of the sclera and a bluish appearance.

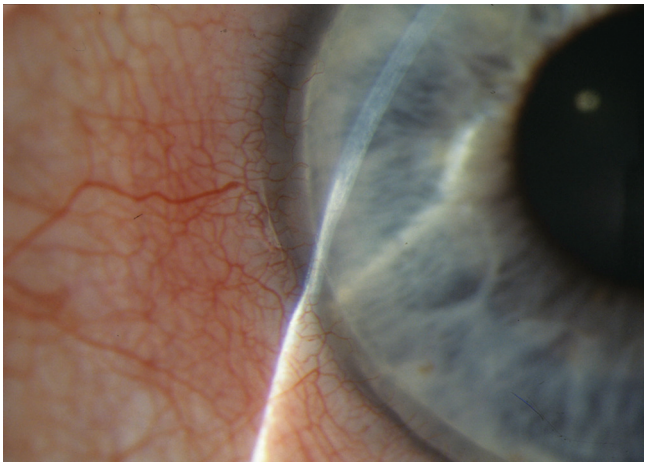

**Figure 44-10** Corneal melt. The white light of the slit lamp beam narrows over the peripheral cornea, where the tissue is thin.

inflammatory bowel disease usually results in control of associated scleritis. Rituximab is reportedly effective for the majority of patients with scleritis who fail to respond to antimetabolite therapy.[33]

## ORBITAL DISEASE

Graves' disease, the most common orbital inflammatory disease, generally results in an orbital myositis that can be identified on imaging such as CT, ultrasound, or MRI. From a rheumatologic perspective, granulomatosis with polyangiitis is the disease that most commonly affects the orbit. The inflammation can be extremely painful and may result in blindness. Orbital inflammation sometimes is more recalcitrant to therapy than other aspects of granulomatosis with polyangiitis. A small series suggested that rituximab may be efficacious in patients with granulomatosis with polyangiitis, including those with orbital involvement.[34]

Orbital pseudotumor, or nonspecific orbital inflammatory disease, is a diagnosis of exclusion that is made on the basis of objective orbital swelling as documented by imaging and a biopsy showing an inflammatory process that cannot be ascribed to another process, such as Graves' disease. A biopsy specimen of the orbit is not always obtained, but it can be useful in ruling out lymphoma or a metastatic malignancy as the cause of the proptosis. Methotrexate is a therapeutic option to treat nonspecific orbital inflammation.[35] Other systemic diseases that commonly affect the orbit include sarcoidosis. Rituximab has been used successfully to treat orbital inflammation that is refractory to antimetabolite therapy.[36]

## OPTIC NEURITIS

Optic nerve disease can result from many insults, including toxins (some of which are medications), vascular insufficiency (such as the insufficiency that occurs as a result of atherosclerotic disease or giant cell arteritis), and immunologic attack. The immune-mediated disease that most commonly affects the optic nerve is multiple sclerosis. This demyelinating condition generally starts suddenly in one eye with pain, an afferent pupillary defect, loss of color vision, and visual field loss typical of optic nerve disease. Initially the optic nerve may show papilledema, or it may appear normal if the inflammation is retrobulbar. Over several weeks, the affected nerve usually becomes pale.

Demyelinating disease affecting the optic nerve generally is not treated by a rheumatologist, but on rare occasions, patients with optic nerve disease have inflammation that might require long-term immunosuppression. These patients carry a diagnosis labeled variously as autoimmune optic neuropathy or, sometimes, steroid-sensitive optic neuropathy. This diagnosis is clinically distinct from optic neuritis associated with multiple sclerosis in that MRI of the head should not indicate a demyelinating process, the disease is often bilateral, the kinetics of the inflammation is different from that of multiple sclerosis, and the disease usually responds to oral corticosteroids. In most centers, a neuro-ophthalmologist would be involved in establishing this diagnosis. Systemic lupus erythematosus and sarcoidosis may affect the optic nerve in this way, but many patients with this diagnosis do not have an associated systemic illness. Therapy with an alkylating agent or an antimetabolite can be beneficial for many patients with this entity.[37]

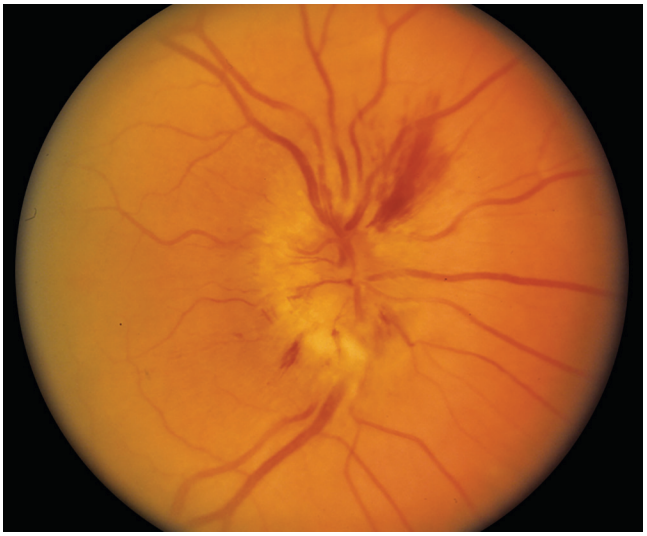

**Figure 44-11** Anterior ischemic optic neuropathy resulting from giant cell arteritis. The optic nerve is swollen, and surrounding hemorrhages are evident.

Sudden blindness is arguably the most feared consequence of giant cell arteritis. This disease is characterized by granulomatous inflammation of multiple vessels above the waist. These vessels frequently include the temporal artery and the posterior ciliary arteries. Inflammation in these latter vessels leads to anterior ischemic optic neuropathy (AION), which is ischemia of the optic nerve that manifests as sudden visual loss (Figure 44-11). Giant cell arteritis also can affect the central retinal artery, which may result in blindness. In this condition, the funduscopic appearance of the eye shows markedly reduced arteriolar flow and a cherry-red spot in the macula. Giant cell arteritis can cause diplopia by affecting circulation to extraocular muscles.

The visual loss associated with giant cell arteritis is frequently labeled arteritic AION to distinguish it from the more common nonarteritic AION, which usually is attributable to small vessel atherosclerosis. Patients with arteritic AION typically are older than 50 years and have an erythrocyte sedimentation rate greater than 50 mm/hr. Many patients with arteritic AION have associated symptoms of polymyalgia rheumatica, jaw claudication, scalp tenderness, or temporal artery tenderness. The biopsy specimen of the temporal artery shows vasculitis in about 80% of patients with giant cell arteritis if an adequate length of vessel is sampled. Twenty percent of patients with giant cell arteritis might have a biopsy specimen of the artery that is negative because the disease has spared this vessel or has affected it in a sufficiently patchy distribution that the biopsy specimen did not reveal the disease. Patients with nonarteritic AION tend to have small optic nerve cups.

## MEDICATION-RELATED OCULAR TOXICITY

A variety of medications have the potential to cause uveitis. These medications include rifabutin,[38] intravenously administered bisphosphonates,[39] moxifloxacin,[40] TNF inhibitors,[41] and ipilumumab.[42]

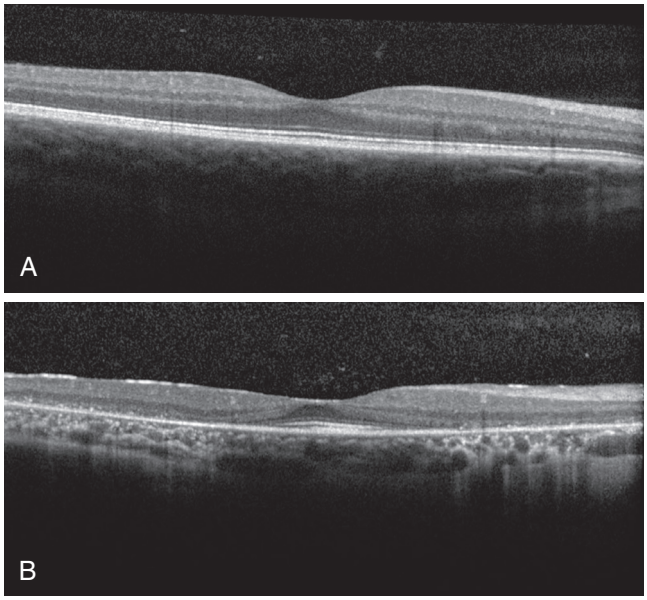

**Figure 44-12** Optical coherence tomography (OCT) demonstrating characteristic changes from antimalarial toxicity. **A,** An OCT of a normal retina. The "valley" at the center of the image is the macula. **B,** Characteristic changes from hydroxychloroquine toxicity. The thinning of the outer nuclear layer in the fovea results in a configuration sometimes called the "flying saucer sign." *(Photograph courtesy Mark Pennesi.)*

Rheumatologists need to be especially aware of the potential for antimalarial agents to cause retinal toxicity. The widespread use of optical coherence tomography (OCT) has resulted in the ability to image retinal layers accurately, quickly, and noninvasively. Although hydroxychloroquine was once considered to be a rare cause of retinal toxicity, OCT studies now show that retinal toxicity is roughly 7.5% among persons who take hydroxychloroquine (see Figure 44-12).[43] The likelihood of toxicity is related to both dosage and duration of therapy.[43] The American Academy of Ophthalmology has revised its recommendations to monitor for antimalarial toxicity. After an initial examination, routine examinations can be deferred until usage reaches 5 years. In addition to a dilated examination and a visual field examination, either OCT, fundus autofluorescence, or multifocal electroretinography, should be used to monitor for toxicity.[44]

## CONCLUSION

In some ways, from a rheumatologist's perspective, the eye is a microcosm of the body. Its complex structures frequently reflect inflammation elsewhere. Treatment of many forms of ocular inflammation requires collaboration between a rheumatologist and an ophthalmologist.

PART 6 DIFFERENTIAL DIAGNOSIS OF REGIONAL AND DIFFUSE MUSCULOSKELETAL PAIN

CHAPTER 45

# Neck Pain

Joseph S. Cheng • Raul Vasquez-Castellanos • Cyrus Wong

**KEY POINTS**

- Neck pain is a ubiquitous condition associated with enormous medical and legal costs.
- Physicians need to differentiate causes of neck pain that can be managed conservatively from causes that require more aggressive treatments.
- Knowledge of the anatomy helps with the diagnosis and the differentiation of symptoms from a musculoskeletal, neurogenic, or vascular cause.
- The history and clinical examination help focus the differential diagnosis and identify the origin of the neck pain based on the anatomy and physiology.
- Indicated imaging studies, neurophysiologic procedures, and laboratory studies aid in diagnosis and in determining a treatment plan for the patient's symptoms.
- In the absence of spinal instability, neurologic deficit, infectious process, or neoplastic process, the patient may benefit from conservative treatment with recovery expected in time.

## EPIDEMIOLOGY

Pain is an evolutionary protective mechanism to prevent further tissue damage. Neck pain is a ubiquitous condition with a lifetime prevalence of 67% to 71%.[1] The annual total cost for neck and low back pain corresponds to 1% of the gross national product in Sweden, with direct health-service costs representing only a small fraction of this percentage.[2-4] The medical and legal expenses associated with neck pain can be enormous, such as in whiplash injuries, which can result in $29 billion in costs annually in the United States alone.[5]

Neck pain may originate from various anatomic structures, including paraspinal soft tissues, the intervertebral joints and disk, compression of the spinal cord or nerve roots, and referred visceral pain. The cause of neck pain has a wide differential diagnosis, which can include trauma, degenerative changes, infection, autoimmune disorders such as rheumatoid arthritis (RA) and ankylosing spondylitis, and lifestyle modifiable factors like smoking. Several studies have identified smoking as the cause of myofascial pain syndromes, including neck pain.[6-11]

The perception and resultant reporting of this pain varies significantly based on cultural and social circumstance. Honeyman and Jacobs[12] noted that Australian Aborigines significantly underreport pain and are rarely disabled by pain. Social circumstances also play an important role in an individual's ability to cope with and overcome neck pain. Studies have demonstrated worse outcomes after diskectomy for patients with a workers compensation claim or litigation surrounding their condition.[13] These studies indicate nonorganic contributions to neck pain for secondary gain. Fortunately, most episodes of acute neck pain resolve with the "tincture of time" and patient education.

Physicians need to be able to differentiate causes of neck pain that can be managed with a conservative approach from those that require more aggressive treatments. An understanding of the anatomy and physiology and their association with the pathogenesis of neck pain provides the basis for obtaining a thorough history, physical examination, and ancillary data with the ultimate goal of effective treatment.

## ANATOMY

The cervical spine consists of seven vertebrae (C1 through C7; Figure 45-1). The bony anatomy of the atlas (C1) and axis (C2) are unique, whereas C3 to C7 demonstrate fairly consistent anatomy.[1] The atlas has no vertebral body; its lateral masses articulate with the skull's occipital condyles, forming the atlanto-occipital joints, which are supported by the anterior and posterior occipital membranes.[14] The atlanto-occipital joint is responsible for approximately 50% of total flexion and extension in the neck, with clear functional implications when this motion is lost. The axis (C2) has the dens or an odontoid peg that projects upward and anterior to articulate with the posterior aspect of the anterior arch of the atlas. The principal stabilizer of the odontoid to the anterior arch of the atlas is the transverse ligament, with the alar and apical ligaments acting as secondary stabilizers. C2 is a true synovial joint and thus is susceptible to inflammatory processes such as RA. There is no intervertebral disk between the atlanto-occipital joint and the atlanto-axial joint, and without the conferred

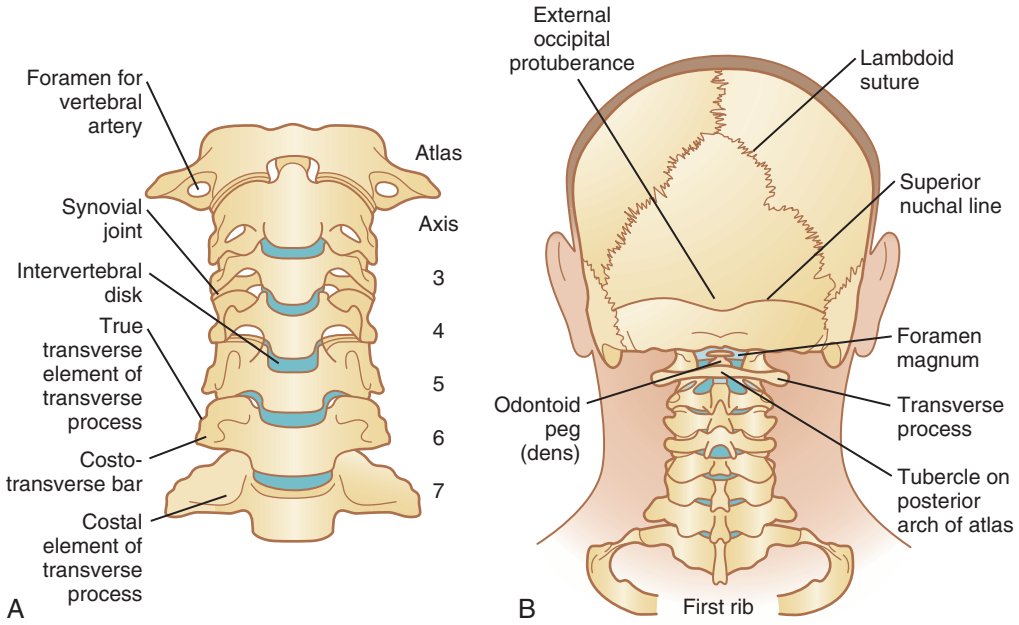

**Figure 45-1** Cervical spine anatomy. **A,** Anterior view. **B,** Posterior view.

stability from a disk, these joints are often affected by destructive inflammatory arthritides, which may result in instability.[15] The atlanto-axial articulation also provides approximately 50% of the rotatory motion of the neck.

The subaxial cervical spine consists of the C3 through C7 vertebrae, which all demonstrate fairly similar anatomy. Each vertebra consists of a body, two interconnecting pedicles, two lateral masses, two transverse processes, two lamina, and spinous processes. The transverse and spinous processes project outward, providing attachment for ligaments and muscles and creating a moment arm to facilitate motion. The spinous processes of C3 through C6 are bifid, whereas the C7 spinous process usually is not bifid. The C7 spinous process is large and the most prominent and easily palpable spinous process below C2.

Five articulations are found between each vertebra from C2 through C7, including the intervertebral disk, two uncovertebral joints, and two facet (zygoapophyseal) joints. The facet joints are true apophyseal joints with hyaline cartilage articulations, intervening menisci, synovial lining, and a joint capsule. This composition makes them susceptible to degenerative changes and systemic arthritides. The cartilage and synovial lining are aneural, whereas the joint capsule is highly innervated by the dorsal primary ramus. The facet joints are angled approximately 45 degrees from the transverse plane, articulating in concert with the uncovertebral joints and ligaments.

The intervertebral disks increase in size from C2 downward, giving the cervical spine its characteristic lordotic shape. Each disk consists of an outer annulus fibrosus and an inner nucleus pulposus, as well as a cephalad and caudal end plate. The annulus fibrosus consists of type I collagen, which gives form to the disk and provides tensile strength. The annulus fibrosus is innervated by the sinuvertebral nerve, formed by branches of the ventral nerve root and the sympathetic plexus.[16] The nucleus pulposus consists of type II collagen and proteoglycans, which interact with water to resist compressive stress. The pressure within the disk is highest with flexion, which may explain why individuals with a disk herniation find this position most uncomfortable.[17] Disk degeneration with aging includes loss of water content with resultant loss of height, annular tears, and myxomatous changes, increasing the risk of disk herniation. This process typically occurs in the posterolateral aspect of the disk, medial to the uncovertebral joints, where the posterior longitudinal ligament is not present and the annulus fibrosus is at its weakest.

The spinal column is supported by an interplay of ligaments and muscles (Figure 45-2). The anterior longitudinal ligament and posterior longitudinal ligament course along the anterior and posterior aspect of the vertebral bodies, with the anterior longitudinal ligament resisting hyperextension and the posterior longitudinal ligament resisting hyperflexion. The ligamentum flavum joins the laminae of adjacent vertebra and with degeneration may buckle and thicken, resulting in spinal canal stenosis and the potential for cord impingement. In a similar manner, the interspinous ligament joins the spinous process of adjacent vertebrae. The supraspinous ligament originates as the nuchal ligament at the occiput and extends caudally as an aponeurosis until it attaches to the tip of the spinous processes of C7 and then continues to the lumbar region. Fourteen paired anterior, lateral, and posterior muscles help orchestrate the complex movements of the neck.

A brief review of the spinal cord and nerve roots is beneficial and assists in performing a thorough evaluation. In general, the spinal cord is divided into the posterior column, the lateral column, and the anterior column. The posterior column mediates proprioceptive, vibratory, and tactile sensation; the lateral column is a conduit for motor fibers, along with pain and temperature sensation from the contralateral side of the body; and the anterior column conveys crude touch sensation. Humans have a total of eight cervical nerve roots as the dorsal and ventral roots converge to form

the spinal nerve within the vertebral foramen. Cervical nerve roots enter the intervertebral foramina by passing over the top of the corresponding pedicle, except the C8 cervical nerve, which lies between C7 and T1. Therefore, a C5-C6 posterolateral disk herniation will affect the C6 nerve root. The nerve root occupies approximately one-third of the foramen (Figure 45-3). The space available for the nerve root is decreased with neck extension and degenerative changes and increased with neck flexion.

The anterior spinal artery arises from the vertebral arteries and supplies the majority of the spinal cord, excluding the posterior columns. The posterior columns receive their blood supply from the two posterior spinal arteries, which originate from either the inferior cerebellar artery or the vertebral arteries. The vertebral arteries arise from the subclavian arteries and course cephalad through the C6 transverse foramen, passing anterior to the emerging cervical nerve root at each level. They pass behind the lateral mass of C1 and enter the foramen magnum. Diseases such as arterial dissection can be associated with severe neck pain and impairment of blood flow through the vertebral artery and can result in posterior circulation signs that include nystagmus, vertigo, drop attacks, dysarthria, and visual impairment. These symptoms are often associated with head position, and if a critical reduction of blood flow occurs, it can result in a cerebellar infarction.

The cervical spine is the most mobile segment of the spine; it has approximately 90 degrees of motion in flexion and extension, with three-fourths of this mobility due to extension (Table 45-1). The maximal range of motion in the sagittal plane within the subaxial spine is at the C5-C6

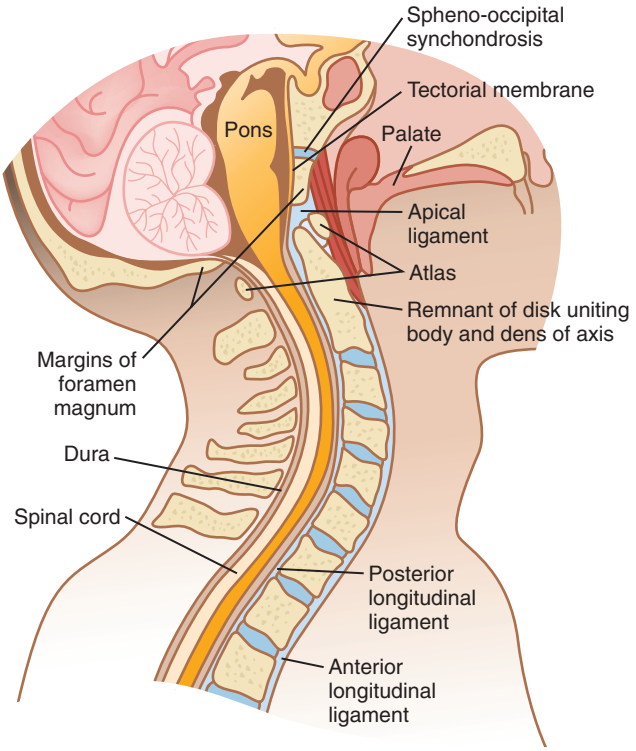

**Figure 45-2** Cervical spine anatomy: sagittal view.

**TABLE 45-1** Age and Normal Cervical Movement

| Age (yr) | Flexion-Extension (degrees) | Lateral Rotation (degrees) | Lateral Flexion (degrees) |
|---|---|---|---|
| <30 | 90 | 90 | 45 |
| 31-50 | 70 | 90 | 45 |
| >50 | 60 | 90 | 30 |

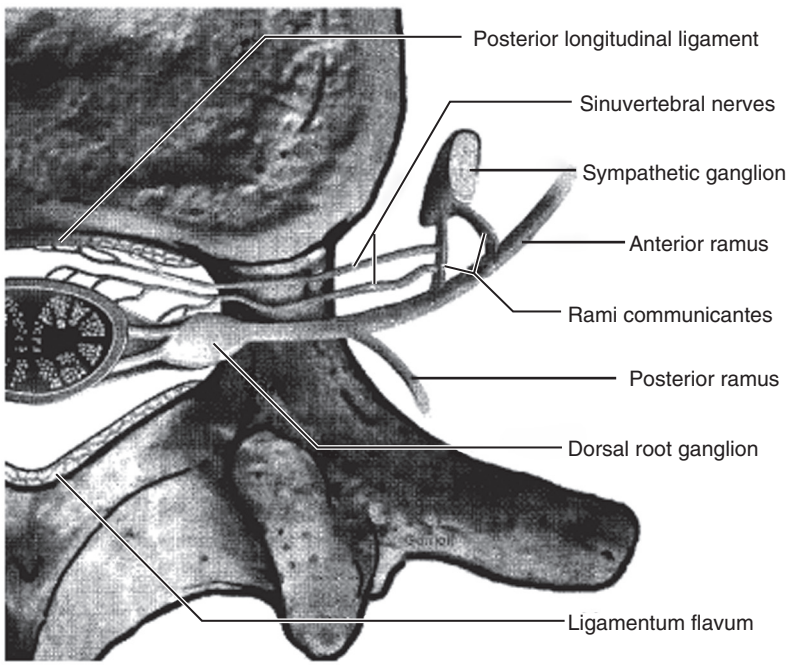

**Figure 45-3** Cervical spine anatomy. *(From Levin KH, editor:* Neck and back pain: continuum 7 [No. 1]. *Philadelphia, 2002, Lippincott Williams & Wilkins, p 9.)*

level, making it a common site of disk degeneration. Rotation encompasses approximately 80 to 90 degrees of motion, with 50% of this motion occurring at the atlanto-axial joint. Much like extension, rotation also reduces the cross-sectional area of the spinal canal. The cervical spine demonstrates 30 degrees of lateral mobility in each direction, which typically occurs with some degree of rotation as a result of the orientation of the facet joints.

## AXIAL NECK PAIN

Axial neck pain may originate from any tissue that receives innervation, including the zygoapophyseal joints, cervical disks, vertebral periosteum, posterior neck muscles, cervical dura mater, occipito-atlanto-axial joints, and the vertebral artery. The cause of neck pain may include degenerative, traumatic, malignant, infectious, and systemic inflammatory processes, as well as smoking. The most direct supporting data available link zygoapophyseal joints and cervical disks to the origin of axial neck pain. Provocative injections into the facet joint in asymptomatic volunteers invoke a reproducible pattern of occipital or axial neck pain.[18] This pattern of pain can be accurately diagnosed and treated, for at least a short period, with anesthetic injections targeted at the joint capsule itself or by blocking its respective dorsal primary ramus.[19-21] Degenerative arthritis within the upper cervical spine can manifest as suboccipital headaches, termed "cervicogenic headaches," which are thought to result from irritation of the greater occipital nerve. Typically arthritis within the atlanto-occipital joints is made worse with provocative neck flexion and extension, whereas atlanto-axial arthritis is made worse with rotation. This phenomenon is supported by a study that found that this pattern of pain was reproduced when asymptomatic volunteers underwent injections at the atlanto-occipital and atlanto-axial joints.[22] Relief of suboccipital pain can be obtained by fluoroscopically guided injection of corticosteroid into the diseased joint, or fusion of these joints in recalcitrant cases.

The cervical disk is a more controversial source of axial neck pain, with pain occurring as a result of insult of the highly innervated annulus fibrosis. This idea is based on provocative diskography, whereby a diseased disk is fluoroscopically injected to a given pressure. A positive test occurs when there is reproduction of pain in reliable patterns. To be a true positive or a "concordant study," an adjacent normal disk should not produce pain when injected. Using this method, several studies have implicated cervical disks as a source of axial neck pain.[16,23,24] Even with use of careful technique, a false-positive finding can occur, and it is not unusual to have a "nonconcordant study" with multiple disks eliciting a pain response despite being normal.[16] Interventions directed at treating the disk for isolated axial neck pain have been found to be unpredictable, despite the fact that the cervical disk likely contributes to axial neck pain.

Myofascial pain due to irritation of the muscles in the neck region can contribute to axial neck pain. Patients with chronic myofascial pain have been shown to have a lower level of high-energy phosphates in the involved muscle tissue.[25] Myofascial pain can be the original source of neck pain or, more commonly, a manifestation of postural adaptations, compensatory overuse of normal tissue that remains after the injured structure heals, and lifestyle habits like smoking. A more generalized form of myofascial pain is fibromyalgia, a widespread disorder defined by diffuse pain that affects all four quadrants of the body, with at least 11 of 18 pressure points being positive. Patients have associated symptoms of fatigue, cognitive difficulties, irritable bowel syndrome, and a nondermatomal pattern of dysesthesias, weakness, and parasthesias.[26]

Systemic inflammatory arthropathies causing neck pain typically demonstrate the classic pattern of morning stiffness, polyarticular involvement, rigidity, and associated cutaneous manifestations. RA often involves the cervical spine, initially causing stiffness and later causing pain and potentially leading to instability. After the hands and feet, the cervical spine is the most common site of disease involvement in RA.[27] The upper cervical spine is most commonly involved (occiput to C2), followed by the subaxial cervical spine (C3 to C7). The likelihood of developing cervical spine disease can be predicted by the amount of rheumatoid changes seen in the hands and feet. Basilar invagination is one such manifestation, whereby the C1 lateral masses erode, allowing the odontoid peg to settle into the foramen magnum and place pressure on the brain stem with the potential for instantaneous death. The atlanto-axial joint can also demonstrate instability with the potential for neurologic injury. Because of these potential catastrophic complications, dynamic radiographs of the cervical spine should be obtained prior to any procedure requiring intubation. The seronegative spondyloarthropathies that can manifest with neck pain include ankylosing spondylitis, psoriatic arthritis, and reactive arthritis. Psoriatic arthritis will manifest with skin lesions before the development of arthritis in 70% of patients, and reactive arthritis rarely involves the cervical spine.

Ankylosing spondylitis often affects the entire axial skeleton with limitation of lumbar motion and chest expansion and later involvement of the cervical spine. In progressive patterns the cervical spine will take on a kyphotic deformity, and as the spine fuses it biomechanically becomes similar to a long bone. As such, minor trauma with neck pain should be taken very seriously in these patients. Even in the face of negative plain radiographs, these patients should undergo an extensive workup with a CT scan, observe strict spine precautions with appropriate neutral alignment according to their baseline spinal curvature, and undergo frequent neurologic evaluations to assess for development of an epidural hematoma.

Infection and neoplasms can cause axial neck pain through bone destruction, with irritation of vertebral body periosteal nerves and altered biomechanics on the facet joints and cervical disks. The onus is on the clinician to identify these patients at the initial visit because a delay in diagnosis can have catastrophic consequences. Red flags for axial neck pain that require further workup at the initial presentation include elderly patients or patients with a history of malignancy, immunocompromised patients, fevers, chills, unexplained weight loss, fatigue, nighttime awakening, recent antecedent bacteremia, and severe nonmechanical neck pain.[26]

Patients who have undergone previous cervical spine surgery should be evaluated for the presence of a pseudoarthrosis or iatrogenic instability. A pseudoarthrosis is failure

of an attempted arthrodesis or fracture to fully heal with bridging bone. These patients describe a "honeymoon" period in which they did well for 3 to 6 months after surgery but then experience worsening axial neck and interscapular pain with associated headaches. Pseudoarthrosis can be diagnosed on plain radiographs with evidence of hardware loosening or movement on dynamic images. A CT scan with coronal and sagittal reconstructions should be obtained to more definitively diagnose a pseudoarthrosis. Once a pseudoarthrosis has been diagnosed, a surgical consult should be obtained, a bone metabolic workup should be undertaken, and the patient should be counseled on smoking cessation, given the deleterious effect of nicotine and carbon monoxide on bone healing. An additional cause of neck pain after surgery is iatrogenic instability, whereby the surgery itself created pathologic motion. This condition requires a surgical consultation to determine if stabilization is warranted.

## RADICULOPATHY AND MYELOPATHY

The clinician must determine if there is evidence of nerve root compression, termed *radiculopathy*, versus a spinal cord compression, termed *myelopathy*. Cervical spondylosis and changes within the disk may cause loss of height with posterior bulging of the disk into the spinal canal and foramen. As the disk collapses, the posterior soft tissue structures, including the ligamentum flavum and facet joint capsule, buckle inward, further compromising the spinal canal and neural foramen. Pressure that was once dispersed throughout the disk is then transferred to the facet joints and uncinate processes, resulting in the development of bone overgrowth or osteophytes, which cause extrinsic pressure on the nerve root or spinal cord.

Radiculopathy is a problem with the peripheral nervous system that affects the exiting nerve root. With radiculopathy, mechanical distortion of the nerve occurs, leading to increased vascular permeability, resulting in chronic edema and eventually fibrosis. This condition leads to hypersensitivity of the nerve root with an inflammatory response mediated by chemicals released from the cell bodies of sensory neurons and the cervical disk.[28] Compression of the dorsal root ganglion is believed to be especially important in producing radicular pain.[29] Clinically, this compression presents with pain in a dermatomal distribution, which is easily identifiable for roots C5-T1. However, dermatomes for the higher cervical nerve roots, including C3 and C4, are along the posterior scapula and should not be confused with isolated axial neck pain.[30] Minor symptoms that are tolerable may be treated with conservative care, but persistent compression on a nerve root can lead to sensory loss and weakness. Disabling deficits should be treated operatively given that prolonged nerve compression can result in irreversible changes. In patients without a neurologic deficit, it is reasonable to expect a good outcome with conservative care.[31]

Myelopathy is a problem with the central nervous system and is a clinical presentation of long tract signs from compression of the spinal cord. Factors that contribute to the development of myelopathy include a congenitally narrow spinal canal, dynamic cord compression, dynamic thickening of the spinal cord, and vascular changes. The anterior-posterior diameter in the subaxial spine for a normal adult measures 17 to 18 mm, with diameters of less than 13 mm considered congenitally stenotic. The cord measures 10 mm. The shape of the spinal cord deformity has a high association with development of myelopathy because patients with a banana-shaped cord on axial views had evidence of myelopathy 98% of the time.[32] Ono and associates[33] described a ratio whereby the anterior-posterior diameter of the spinal cord is divided by the transverse diameter of the cord. Patients with a ratio of less than 0.40 tended to have severe neurologic deficits.[33] Certain patients may have dynamic cord compression with signs and symptoms of myelopathy only during neck flexion and extension. The space available for the cord is decreased during neck extension because of infolding of the ligamentum flavum and overlapping of the lamina. Also during extension, the spinal cord shortens as the distance from the skull base to the cervical spine is lengthened, effectively increasing cord diameter and making it more prone to compression by the posterior structures. In flexion, the cord lengthens and drapes over anterior degenerated disks and osteophytes.[34]

Myelopathy can be exacerbated by altered biomechanics from degenerated segments. For example, when a given level stiffens, the level above can become hypermobile.[35] A certain subset of patients can experience myelopathy in the absence of mechanical compression, which has been attributed to ischemic insult.[36] Despite the prevalent theory of ischemia, the precise molecular mechanisms that contribute to the development of myelopathy are not completely known. Some studies have debated the role of ischemia, proposing a complex cascade of bimolecular events that leads to the disease.[37] Patients with mild cases of myelopathy that do not affect activities of daily living can be closely monitored.[38] Patients with more severe deficits or progressive deficits tend to deteriorate over time with conservative care, and it is recommended that these patients undergo surgery to decompress the spinal cord.[39]

### Infection/Neoplasm

Outside the degenerative cascade, infection and neoplasm can be the source of axial neck pain or neurologic deficit. In terms of infection, several entities are often seen: diskitis, osteomyelitis, or epidural abscess. Risk factors for infections of the spine include immunosuppression, intravenous drug use, and alcohol abuse, among others. Infection can also spread after lumbar puncture or epidural anesthesia.

The most common symptoms of spinal infection include excruciating pain and tenderness, accompanied by constitutional symptoms, including fever, night sweats, and lethargy. Disease progression may eventually lead to neurologic deficits such as motor deficits, sensory loss, and bowel/bladder dysfunction. Neurologic deficits are more common with epidural abscesses and are less commonly seen with osteomyelitis and diskitis. Whether CT or MRI scans are performed, contrast is needed in the setting of infection. MRI best evaluates epidural abscesses, but if no deficit is seen, CT may help with evaluating the bony destruction and mechanical instability.

The most common organisms seen in spinal infections include *Staphylococcus aureus*, streptococcus, *Escherichia coli*, *Pseudomonas aeruginosa* (especially in intravenous drug

abusers), and *Haemophilus influenza* (pediatric diskitis). In 29% to 50% of the cases an organism is not identified, especially when antibiotics have been started.[40]

Diskitis and osteomyelitis often can be treated nonsurgically. Long-term treatment with antibiotics in combination with bracing often can treat the underlying infection and avoid progressive deformity.[40] The antibiotics used most often include vancomycin, rifampin, and a third-generation cephalosporin for 4 to 6 weeks with or without an oral agent. These patients are watched closely for progression of disease—that is, worsening pain or neurologic deficit—and also are monitored with serial inflammatory markers, such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). Because of the nature of the antibiotics and the prolonged treatment time, kidney function must be monitored as well. Refractory infections and/or suspected instability cases should be referred for a surgical consultation.

Because of their proximity to the spinal cord and high chance for rapid neurologic deterioration, epidural abscesses have a lower threshold for surgical treatment, and a surgical consultation should always be considered.[40-43] Nonsurgical management is indicated in the neurologically intact patient with a small abscess or in patients too unstable for surgery.[40] In the setting of a progressive deficit or large abscess, the main goals of surgery are to decompress the neural elements and disrupt the abscess capsule, which helps with antibiotic penetration and infection control.

Neoplasms represent another source of neck pain. Similar to infection, neoplastic processes cause axial neck pain through bone destruction and irritation of periosteal nerves and altered biomechanics of facet joints and the anterior column, leading to progressive cervical kyphosis. The spine is the most frequent site of bone metastases, and spinal metastases will develop in 5% to 10% of patients with cancer.[44-47] Common tumors that metastasize to the spine are lung, breast, and prostate. A smaller percentage of cervical spine tumors are primary spinal tumors, including ependymomas, astrocytomas, schwannomas, neurofibromas, or meningiomas. Spinal cord tumors are often classified based on location: extradural, intradural-extramedullary, or intramedullary. MRI with contrast is the imaging modality of choice to visualize the tumor. Consultation with a spine surgeon should be requested in all neoplasm cases.

Treatment of spinal tumors is based on tumor disease, neural compression, and the presence of instability. The main driver of treatment in terms of tumor biology is its radiosensitivity. Radiosensitive tumors can be emergently treated with radiation even in the setting of compression of neural elements. The most common radiosensitive tumors include lymphoma and multiple myeloma. Stereotactic radiation is becoming increasingly popular as a method of maximizing radiation to the surrounding tumor without damaging the sensitive spinal elements.[48-51] For metastatic spinal tumors causing spinal cord compression, the standard of treatment is surgical decompression followed by radiation.[52]

## CLINICAL FEATURES

In terms of functional anatomic pathways, neck pain is mediated via somatic or autonomic pathways.[53] Somatic pain, the most common, is perceived in dermatomes, myotomes, or sclerotomes. Pain originating in the autonomic pathway, or sympathetic nervous system, may fall into somatic segmental distributions, vascular supply distributions, peripheral nerve distributions, or nonconforming patterns. Because pain mediation pathways may have significant overlap, additional clinical information regarding characteristics of the neck pain along with diagnostic studies will complement the determination of the pain origin.

### Patient History

Neck pain is the most common symptom of cervical spine disease, and correctly characterizing it helps to identify conditions requiring immediate treatment. Important characteristics to note include onset, distribution, frequency, duration, quality, aggravating factors, and the presence of neurologic symptoms. In general, pain that is present only intermittently may be indicative of instability or motion, whereas constant and increasing pain is a source of concern for a mass effect. The new onset of generalized neck pain that is of relatively short duration is likely related to benign disease, including muscle strain, whereas a longer duration of symptoms indicates significant or progressive disease. A well-localized quality of pain indicates specific nerve root irritation, whereas poorly defined pain may derive from irritation of deep connective tissue structures such as muscle, joint, bone, or disk. Aggravating and relieving factors may help elucidate biomechanical changes in the cervical spine that are contributing to the symptomatology.

Localized axial neck pain is commonly reported as originating posteriorly with extension into the shoulder or occiput. Localized pain of myofascial origin may worsen with neck flexion, whereas diskogenic neck pain will worsen with neck extension or rotation. Referred pain to the occiput usually indicates pathologic changes in the upper cervical spine and may radiate down the neck and to the ear. Shoulder girdle pain develops as a result of postural adaptations from initial neck pain symptoms. It is not uncommon for pain to be referred from the shoulder, heart, lungs, viscera, or temporomandibular joint to the neck region because of overlapping nerve distribution. Symptoms may arise as a result of irritation or activation of receptors directly, as with articular pain, pseudoarticular pain, vascular pain, cervicogenic headaches, pseudoangina pectoris, eye and ear symptoms, and throat symptoms.

Articular symptoms arise from innervation to the facet and uncovertebral joints, causing local pain and stiffness. Patients often state that their symptoms are made worse with inactivity and describe feelings of clicking, grating, or "sand" in the neck. Pseudoarticular pain may be felt in the shoulder and elbow, with the true disease originating from the neck. Vascular symptoms result from compression of the vertebral artery by osteophytes or a protruding disk. Symptoms may intensify with neck movement or certain postures. Tenosynovitis and tendonitis may involve the rotator cuff and tendons about the elbow, wrist, or hand. Stenosis or fibrosis of tendon sheaths or palmar fascia may be present, along with trigger points over the affected joints, giving a false impression of local disease.[54]

**TABLE 45-2** Cervical Nerve Root Segments and Corresponding Clinical Signs

| Nerve Root | Symptom | Correlate |
|---|---|---|
| C3<br>C4 | Suboccipital pain with extension to the back of the ear<br>Pain from the caudal aspect of the neck to the superior aspect of shoulder | If C3, C4, and C5 are all involved, paradoxical breathing might occur |
| C5 | Numbness over the shoulder and down the lateral aspect of the arm to the mid portion; the deltoid muscle may be weak and the biceps reflex may be affected | |
| C6 | Radiating pain and numbness down the lateral aspect of the arm and forearm to the thumb and index finger ("six shooter"); weakness in wrist extension, elbow flexion, and supination; diminished brachioradialis and biceps reflex | Sensory component can mimic carpal tunnel syndrome |
| C7 | Numbness and pain down the posterior aspect of the arm and forearm to the long finger; weakness in the triceps, wrist flexion, and finger extensors | Most frequent; posterior interosseous nerve entrapment can mimic motor component, but no sensory deficits are present |
| C8<br>T1 | Pain and numbness down the medial aspect of the arm and forearm into the 4th and 5th digits; weakness in the flexor digitorum profundus to IF and LF and FPL | AIN entrapment can mimic motor component of C8 or T1; however, sensory changes and involvement of thenar muscles will not be present; ulnar nerve entrapment will spare short thenar muscles with the exception of ADP; does not involve FPL or FDP to IF and LF |

ADP, Adductor pollicis; AIN, anterior interosseous nerve; FDP, flexor digitorum profundus; FPL, flexor pollicis longus; IF, index finger; LF, long finger.

## Localization of Pain Generators

Pain may be somatic or autonomic and is not always felt in precise anatomic zones. Overlapping sensory supplies may be present, as well as radiation in spinal segments by recruitment within the spinal column, causing difficulty in localization. Somatic pain is caused by cervical nerve root irritation. It is the most common type of pain, and diabetics are more susceptible to this nerve root irritation. Neurologic deficits correspond with the offending disk level in 80% of patients.[55]

Neuralgic and myalgic pain describes symptoms resulting from compression of different areas of the nerve root. Neuralgic pain originates from irritation of the dorsal sensory root and has a "lightning" or "electric" sensation that tends to be dermatomal and associated with numbness and paresthesias. The pain tends to present more proximally, with paresthesias more distally. Myalgic pain occurs with irritation of the ventral motor root. This pain is described as a deep, boring, and unpleasant sensation that tends to be poorly localized because of its referral to sclerotomal areas. These sensations conform to the areas of muscles that are innervated by the compressed nerve root. Autonomic-mediated symptoms result in dizziness, blurring of vision, tinnitus, retroocular facial pain, and jaw pain.

It is important to determine if the axial neck pain is isolated or if there is associated radiating pain, weakness, changes in sensation, or alterations in proprioception. The compression of a nerve root often can be localized by identifying the distribution of pain, paresthesia, or weakness as it follows segmental distribution of that respective nerve root (Table 45-2). Sensory loss may be described by the patient in precise terms with a description of numbness, or alternatively the patient may have vague symptoms of swelling or bogginess to the skin. If the face, head, or tongue is involved, the upper three nerve roots of the cervical plexus may be affected. Numbness of the neck, shoulder, arm, forearm, or fingers indicates involvement of C5-T1. Weakness, as with sensory changes, occurs in a graded fashion depending on the amount of compression on the nerve root. This weakness will present clinically with an obvious functional deficit or more subtle findings, made obvious only after repetitive testing. The clinician must be attuned to these subtle complaints of weakness, which may be described by the patient as a feeling of heaviness of the limbs, early fatigue, or insufficient power in the grip. If obvious atrophy is present in a muscle, then more than one nerve root is affected because of the evolutionary benefit of multiple levels of innervation for a given muscle. Alterations in proprioception are due to compression of the dorsal column of the spinal cord and will be described by the patient as symptoms of clumsiness, with reports of tripping or dropping objects. This presentation raises concern for the more ominous condition of myelopathy, which is secondary to spinal cord compression.

Cervical spinal disease classically causes isolated axial neck pain or a radicular pain that radiates to the shoulder or down the upper extremity (Table 45-3). However, less commonly it can be the cause of headache, pseudoangina pectoris, and otolaryngologic sensations. Cervicogenic occipital headaches can be compounded by adaptive changes in the posterior occipital muscles and often spread

**TABLE 45-3** Cervical Nerve Root Pain Referral Pathways

| Location of Pain | Source |
|---|---|
| Upper posterolateral cervical region | C0-C1, C1-C2, C2-C3 |
| Occipital region | C2-C3, C3 |
| Upper posterior cervical region | C2-C3, C3-C4, C3 |
| Middle posterior cervical region | C3-C4, C4-C5, C4 |
| Lower posterior cervical region | C4-C5, C5-C6, C4, C5 |
| Suprascapular region | C4-C5, C5-C6, C4 |
| Superior angle of scapula | C6-C7, C6, C7 |
| Midscapular region | C7-T1, C7 |

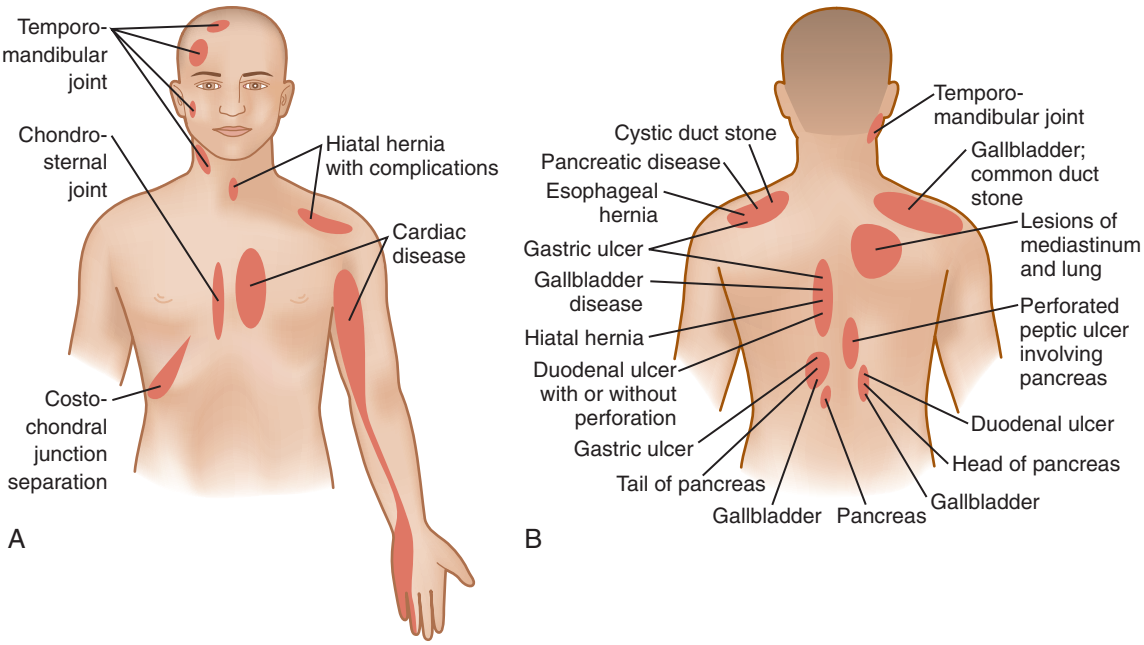

**Figure 45-4** Patterns of referred pain. **A,** Anterior distribution. **B,** Posterior distribution.

to the eye region, manifesting as a dull rather than a pulsating pain. These headaches are unique in that they are aggravated by neck movements. They typically have migraine-like symptoms, including phonophobia or photophobia.

Pseudoangina pectoris has been reported as a result of cervical spinal disease and can be confused with angina pectoris or breast pain in women (Figure 45-4). In the presence of a C6-C7 lesion, neuralgic or myalgic pain may be present along with tenderness in the precordium or scapular region. Differentiation of heart disease from symptoms associated with C6-C7 dysfunction is made on the basis of muscle weakness, fasciculations, sensory changes, or reflex changes. Differentiation of these two diseases may be difficult when true angina and pseudoangina coexist in the same patient.[56]

Cervical spinal disease may manifest in the form of eye, ear, and throat symptoms (Figure 45-4). Eye and ear symptoms may arise from irritation of the plexuses surrounding the vertebral and internal carotid arteries. Eye symptoms can present with blurring of vision relieved by changing neck position, increased tearing, orbital and retro-orbital pain, and descriptions of eyes being "pulled backward" or "pushed forward." Altered equilibrium with associated gait disturbances may result from irritation of surrounding sympathetic plexus or vertebral insufficiency. Hearing can be affected with tinnitus and altered auditory acuity. Throat symptoms, including dysphagia, may be related to anterior vertebral osteophytes that cause direct compression, as well as cranial nerve and sympathetic nerve communications.

Symptoms of dyspnea and cardiac arrhythmia and drop attacks may have a cervical spinal origin. Dyspnea can be related to a deficit in C3-C5 innervation of the diaphragm. Cardiac palpitations and tachycardia resulting from cervical spine disease can be differentiated from other causes by the fact that these symptoms are associated with unusual positions or hyperextension of the neck. This presentation is caused by irritation of C4 innervation of the diaphragm and pericardium or irritation of the cardiac sympathetic nerve supply. Drop attacks suggest posterior circulation insufficiency, resulting in an abrupt loss of proprioception without the loss of consciousness.

Myelopathy, or spinal cord compression, initially presents with subtle complaints of hand clumsiness or difficulty with balance. Patients will report worsening handwriting in the past few months or difficulty buttoning shirts. Patients also may have nausea and emesis caused by equilibrium dysfunction. Paresthesias and dysesthesias may be present, often involving bilateral upper extremities and not following a dermatomal distribution. This presentation is often mistaken for peripheral neuropathy or carpal tunnel syndrome but should be considered when bilateral extremity symptoms are present. As the disease progresses over time, more advanced manifestations occur, including most commonly weakness in the triceps, hand intrinsic, and hip flexors. Late manifestations include spasticity, as well as bowel and bladder dysfunction.

Finally, neck pain may present concomitant with systemic disease with varied symptoms that require further investigation. Examples include inflammatory arthritides, infection or tumor, multiple sclerosis, subacute combined degeneration, or syrinx. Inflammatory arthritides often present with morning stiffness, polyarticular involvement, or cutaneous manifestations. Fever, weight loss, or night pain points to an infectious or neoplastic cause. A Pancoast's tumor is a neoplastic process of the apical portion of the lung that can cause a mass effect on the caudal cervical nerve roots. This tumor should always be considered in a person with radicular symptoms and a history of smoking, with workup including a chest radiograph. Idiopathic brachial plexus neuritis, formerly known as Parsonage-Turner syndrome, is caused by viral infection of the brachial plexus that presents with severe arm pain involving multiple nerve

roots. The classic presentation is weakness and variable deficits after the acute phase of severe pain resolves. Subacute combined degeneration from $B_{12}$ deficiency is a consideration when greater sensory deficit is present in the lower extremities.

## Clinical Examination

A careful clinical examination provides additional focus to the differential diagnosis. The clinical examination begins by broadly observing the patient's gait, as well as his or her head and neck posture. Results of further palpation, range of motion testing, and a neurologic examination for motor signs, reflexes, sensory signs, autonomic signs, and articular signs are assessed (Table 45-4).

Careful palpation with knowledge of key anatomic bony and soft tissue landmarks in the cervical spine may localize pain to a particular cervical level and location. Anteriorly or anterolaterally, the transverse process of C1 is palpated between the angle of the jaw and the styloid process. C3 is identified by palpation of the hyoid bone. C4-C5 is at the level of the thyroid cartilage, and C6 is at the level of the cricoid ring and the carotid tubercle. In the process of examining the neck, the sagittal balance with retention or loss of normal cervical lordosis also should be noted. Posteriorly and posterolaterally, the occiput, inion, superior nuchal line, mastoid processes, and spinous processes of C2 and C7-T1 are palpable.

Soft tissues about the anterior and posterior triangles of the neck, occipital region, and posterior paraspinal muscles

**TABLE 45-4** Nerves and Tests of Principal Muscles

| Nerve | Nerve Roots | Muscle | Test |
|---|---|---|---|
| Accessory | Spinal | Trapezius | Elevation of shoulders<br>Abduction of the scapula |
| | Spinal | Sternocleidomastoid | Tilting of the head to the same side with rotation to the opposite side |
| Brachial plexus | | Pectoralis major | |
| | C5, C6 | Clavicular part | Adduction of the arm |
| | C7, C8, T1 | Sternocostal part | Adduction, forward depression of the arm |
| | C5, C6, C7 | Serratus anterior | Fixation of the scapula during forward thrusting of the arm |
| | C4, C5 | Rhomboid | Elevation and fixation of the scapula |
| | C4, C5, C6 | Supraspinatus | Abduction of arm initiated |
| | (C4), C5, C6 | Infraspinatus | External rotation of the arm |
| | C6, C7, C8 | Latissimus dorsi | Adduction of horizontal, externally rotated arm, coughing |
| Axillary | C5, C6 | Deltoid | Lateral and forward elevation of the arm to the horizontal position |
| Musculocutaneous | C5, C6 | Biceps<br>Brachialis | Flexion of the supinated forearm |
| Radial | C6, C7, C8 | Triceps | Extension of the forearm |
| | C5, C6 | Brachioradialis | Flexion of the semiprone forearm |
| | C6, C7 | Extensor carpi radialis longus | Extension of the wrist to the radial side |
| Posterior interosseous | C5, C6 | Supinator | Supination of the extended forearm |
| | C7, C8 | Extensor digitorum | Extension of the proximal phalanges |
| | C7, C8 | Extensor carpi ulnaris | Extension of the wrist to the ulnar side |
| | C7, C8 | Extensor indicis | Extension of the proximal phalanx of the index finger |
| | C7, C8 | Abductor pollicis longus | Abduction of the first metacarpal in plane at a right angle to the palm |
| | C7, C8 | Extensor pollicis longus | Extension of the first interphalangeal joint |
| | C7, C8 | Extensor pollicis brevis | Extension of the first metacarpophalangeal joint |
| Median | C6, C7 | Pronator teres | Pronation of the extended forearm |
| | C6, C7 | Flexor carpi radialis | Flexion of the wrist to the radial side |
| | C7, C8, T1 | Flexor digitorum superficialis | Flexion of the middle phalanges |
| | C8, T1 | Flexor digitorum profundus (lateral part) | Flexion of the terminal phalanges, index, and middle fingers |
| | C8, T1 | Flexor pollicis longus (anterior interosseous nerve) | Flexion of the distal phalanx, thumb |
| | C8, T1 | Abductor pollicis brevis | Abduction of the first metacarpal in plane at right angle to the palm |
| | C8, T1 | Flexor pollicis brevis | Flexion of the proximal phalanx, thumb |
| | C8, T1 | Opponens pollicis | Opposition of the thumb against the fifth finger |
| | C8, T1 | First and second lumbricals | Extension of the middle phalanges while the proximal phalanges are fixed in extension |
| Ulnar | C7, C8 | Flexor carpi ulnaris | Observation of tendons during testing of abductor digiti minimi |
| | C8, T1 | Flexor digitorum profundus (medial part) | Flexion of distal phalanges of the ring and little fingers |
| | C8, T1 | Hypothenar muscles | Abduction and opposition of the little finger |
| | C8, T1 | Third and fourth lumbricals | Extension of the middle phalanges while the proximal phalanges are fixed in extension |
| | C8, T1 | Adductor pollicis | Adduction of the thumb against the palmar surface of the index finger |
| | C8, T1 | Flexor pollicis brevis | Flexion of the proximal phalanx, thumb |
| | C8, T1 | Interossei | Abduction and adduction of the fingers |

are examined. The sternocleidomastoid muscle is involved with whiplash injuries, whereby abrupt hyperextension of the neck occurs. The muscle may be tender to palpation, or the patient may be splinting the neck with the head turned away from the injured muscle. This posturing of the neck is termed *torticollis*, and the clinician should remember that the head is turned away from the side of the involved sternocleidomastoid. Flexion injuries may traumatize the trapezius muscle. Midline cervical tenderness is more of a concern for ligament injury, whereas paraspinal muscle tenderness is typically a more benign process.[57] The greater occipital nerves are located lateral to the inion and may be involved in traumatic inflammation associated with flexion or extension injuries resulting in suboccipital headaches. Skin markings or visible trauma should be noted at this time.

Range of motion examination may reveal pain or limitations in flexion-extension, lateral bending, and rotation. Flexion limitation may be assessed by placing fingers between the patient's chin and sternum at maximum flexion, with 50% the motion occurring at the occiput-C1 joint and the remaining 50% distributed over C2-C7. If the patient is unable to place the chin on the chest, the interval should be measured. One finger width shows a limitation of 10 degrees, whereas three fingers width indicates a 30- degree limitation in flexion. Upon extension the distance between the base of the occiput and the spinous process of T1 should be measured. Lateral flexion should allow the ear to touch the shoulder, with motion being shared across all cervical vertebrae. Upon rotation, the chin should touch the shoulder, with 50% of rotation occurring at C1-C2 and the remaining 50% distributed in the subaxial spine between C3-C7. A natural decrease in range of motion occurs with age, even in healthy individuals.[58]

Range of motion tests the ligaments, capsules, and fascia, and range of motion will be reduced in the presence of cervical spinal muscular spasm or pain. Patients with degenerative changes of the cervical spine will have back pain with decreased range of motion of the cervical spine without resistance. The most common findings due to changes in the cervical spine articulations are (in order): restriction of movement with or without pain, pain upon movement, and local tenderness. Lateral flexion is the earliest and most impaired movement in degenerative diseases, with rotation first impaired in RA because of involvement of the odontoid peg. A uniformly stiff neck may be caused by diffuse idiopathic skeletal hyperostosis, which is present in a quarter of elderly patients but also may be due to ankylosing spondylosis or recent trauma to the neck.[59] If articular signs are found, the examiner must evaluate the entire vertebral column and peripheral joints for evidence of further arthritis and search for extra-articular manifestations.

Motion against resistance testing is performed after active and passive range of motion is established. Muscle groups tested include the flexors and extensors of the neck. In testing flexor muscles, a hand is placed between the forehead and chest. The primary flexor is the sternocleidomastoid muscle, with secondary flexors being the three scalene muscles and small pre-vertebral muscles. Extensor muscles are tested by placing a hand on the shoulder and head for resistance. Primary extensors include the paravertebral extensor mass, splenius, semispinalis capitis, and trapezius. Secondary flexors include the small intrinsic muscles of the neck. Rotators are examined by placing a hand on the shoulder and chin for resistance. The sternocleidomastoid muscle and the intrinsic muscles of the neck provide rotational force. Motion against resistance testing should include an active maximum effort strength testing to the extremes of flexion, extension, and rotation to assess muscle strength. Causes of decreased range of motion of the cervical spine include joint locking and bony ankylosis from degenerative changes or arthritides, fibrous contractures, muscle spasm, and splinting over painful joints, as well as nerve root or spinal cord compression or irritation. Decreased range of motion in the presence of pain or weakness warrants further investigation.

Sensation for light touch, pinprick, temperature, and proprioception should be performed. These tests are admittedly subjective, and therefore both extremities should be compared to assess differences in sensation. Comparing an unaffected area such as the face to the area of decreased sensation can also be helpful. Pinprick can be performed using a sterile needle, and temperature using an alcohol pad can be used to assess functioning of the spinothalamic tract that traverses the anterolateral aspect of the spinal cord. Light touch and proprioception assess functioning of the posterior spinal column.

Dermatomes are anatomically distributed, as noted in Figure 45-5. The lower extremities demonstrate a unique dermatomal map that correlates with embryologic development whereby the limb starts in a supinated position and with longitudinal growth pronates. Perineal sensation and rectal tone are important to examine because an abnormality may indicate compression of the spinal cord or cauda equina, requiring immediate surgical intervention. Isolating the level of disease can at times be challenging. Nerve roots with proximal compression are more susceptible to distal compression. When the nerve is compressed both proximally and distally it is called a "double crush" phenomenon. The cervical spine should always be considered as the potential etiology in patients who present with symptoms of carpal or cubital tunnel syndrome and peripheral neuropathy. Ancillary imaging and nerve conduction studies can help elucidate the cause.

After palpation, range of motion testing, and assessment of sensation, muscle strength testing is continued for localization of any positive findings. Lower motor neuron disease is indicated by weakness, hypotonia, and fasciculations. Upper motor neuron disease is indicated by spasticity. Motor function should be graded using the standard 0-5 nomenclature: grade 0, no function; 1, a trace of function; 2, full range of joint motion with gravity eliminated; 3, antigravity function; 4, function against slight resistance; and 5, normal strength against resistance (Table 45-5). If weakness is

**TABLE 45-5** Strength Grading in Motor Examination

| | |
|---|---|
| 0 | No function with total paralysis |
| 1 | Trace movement with palpable or visible contraction |
| 2 | Full range of joint motion with gravity eliminated |
| 3 | Active movement against gravity |
| 4 | Active movement against slight resistance |
| 5 | Normal strength |

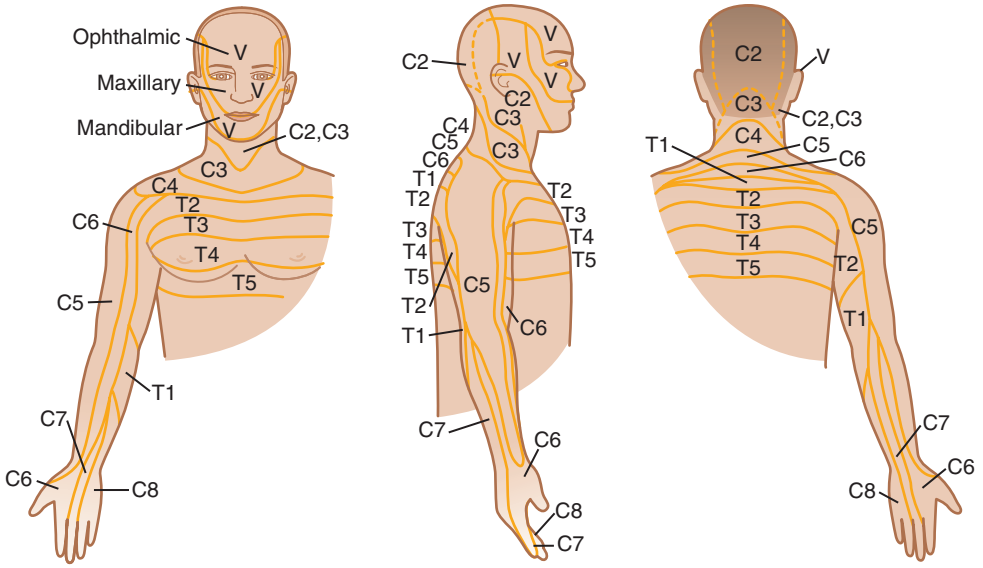

**Figure 45-5** Dermatome distributions. Dermatome distribution of nerve fibers from C1 through T5, carrying senses of pain, heat, cold, vibration, and touch to the head, neck, arm, hand, and thoracic area. The sclerotomes and myotomes are similar but show some overlap. Pain arising from structures deep to the deep fascia (myotome and sclerotome) does not precisely follow the dermatome distribution.

present, a more focused examination should be performed to look at other muscles innervated by that same nerve root.

Deep tendon stretch reflexes should be performed and graded from 0 to 3, as follows: 0, no response; 1, hyporeflexive; 2, normal; and 3, hyperreflexive. C5 is tested by striking the biceps tendon; C6, the brachioradialis; C7, the triceps; L4, the patellar tendon; and S1, the Achilles tendon. To facilitate reflex testing, it may be helpful to use muscle loading or Jendrassik's maneuver (performed by having the patient flex both sets of fingers into a hook-like form, interlocking the hands, and pulling apart). This technique creates a diversion to help relax the patient and better assess lower extremity reflexes. If difficulty with reflex testing persists, one must ensure that no peripheral neuropathy is present. In addition to deep tendon reflex testing, the abdominal reflex, Babinski test, and bulbocavernosus test should also be assessed.

Provocative tests that can be helpful in confirming compressive extradural monoradiculopathy include Spurling's test, the arm abduction test, and the axial compression and traction test. All of these tests are meant to change the diameter of the neural foramen, thus increasing or decreasing the symptoms, respectively. Spurling's test is performed by having the patient extend his or her neck and rotating toward the side of pain. The test is positive if the radicular pain is made worse in this position and indicates foraminal stenosis with potential compression of a nerve root. The arm abduction sign is positive if the patient's pain is relieved by placing the hand on the affected side, on top of the head.[60] The axial compression test is performed by pressing on top of the patient's head with the neck in the neutral position, with a positive result if the radicular symptoms are exacerbated by this maneuver and relieved by placing traction on the head and opening up the foramina.

Provocative tests that are helpful in diagnosing myelopathy include the presence of Hoffmann's sign, the finger escape sign, the abnormal grip-release test, and Lhermitte's sign. A positive (pathologic) Hoffmann's sign is performed by holding the middle finger extended and suddenly extending the distal interphalangeal joint, resulting in flexion of the index finger and thumb. A positive finger escape sign occurs when a person cannot hold all of the fingers in an adducted and extended position without the ulnar two digits falling into flexion and abduction over time. The grip-release test reveals an inability to rapidly open and close a fist because of weakness and spasticity of the hand. Lhermitte's sign evaluates changes in the spinal cord itself and occurs when the patient's neck is forcefully flexed, resulting in electric-like shocks that travel down the arms and legs. This reaction indicates changes in the white matter of the spinal cord and may be a result of cervical myelopathy or multiple sclerosis.

## DIAGNOSTIC EVALUATION

After completing the history and clinical examination, performing indicated imaging studies, neurophysiologic procedures, and laboratory studies may aid in completing the differential diagnosis and treatment plan for the patient's neck pain. Cervical radiographs often show degenerative changes in asymptomatic people in their sixties.[61] In the absence of trauma, constitutional symptoms, or worsening neurologic deficit, 4 to 6 weeks of conservative care is indicated prior to obtaining radiographs.[62] Dynamic radiographs should also be used for screening patients with RA prior to endotracheal intubation, given the risk of cervical instability. One study demonstrated that 61% of patients with RA had evidence of instability defined by at least 3 mm of atlanto-axial subluxation on pre-operative screening radiographs.[63]

In the presence of significant degenerative changes and end plate osteophytes, CT myelography can be helpful in further characterizing the bony involvement. CT myelography should be thought of as a complimentary test to MRI.[64]

It should only be used as the primary test to evaluate neural involvement when MRI is contraindicated because MRI is superior for evaluating spinal cord changes such as syringomyelia, myelomalacia, or neoplasm.[65] MRI scanning is indicated for progressive neurologic deficit, disabling weakness, or long tract signs and is recommended for patients with persistent cervical radiculopathy after 6 weeks of conservative care.[62] The addition of gadolinium contrast enhancement is helpful in evaluating infection and neoplasm and differentiating scarring from recurrent disk herniation in patients who have undergone previous spinal surgery. MRI results must be correlated with physical examination findings given that asymptomatic volunteers have been found to have abnormal cervical spine MRI findings.[53] Increased signal on the T2 sequence can be representative of a spectrum of disease from edema to myelomalacia and syrinx formation. Therefore the presence of increased signal within the spinal cord warrants a surgical consultation and operative intervention if the examination and history correlate, or close follow-up at a minimum. If the MRI findings do not correlate with the history and physical examination findings, further studies may be required, such as CT myelography. CT myelography is superior at detecting bony foraminal stenosis. Nuclear bone scanning techniques, including the single photon emission computerized tomography scans, have been used to identify and characterize acuity in occult fractures, periosteal injury, and post-traumatic osteoarthritis in the absence of positive radiograph findings.[66]

Neurophysiologic procedures are indicated when the clinical examination and imaging studies fail to correlate or when there is conflicting information. Electromyography (EMG), nerve conduction studies, and somatosensory evoked responses help differentiate cervical spine disorders from peripheral nerve entrapment syndromes and help in differentiating intrinsic joint disease from a radiculopathy. These tests are complementary to plain radiographs and an MRI scan or CT myelogram.

Neck pain is typically a result of mechanical causes, and laboratory studies generally are not helpful in its diagnosis. However, laboratory studies can be critical in ruling out infection, neoplasm, and systemic arthritides. ESR indirectly measures the acute-phase response with a high sensitivity but low specificity. Patients younger than 50 years should have an ESR less than 20 mm/hour, with the accepted normal range increasing as the patient ages. Values greater than 100 are seen with infection and neoplasm, whereas less dramatic elevations are seen with RA and after surgery.[67] CRP is an acute-phase reactant synthesized by the liver, with elevations peaking by day 2 of the inciting event and returning to normal within 3 to 7 days of removing the insult.[68] The complete blood cell count with differential and a spinal tap can also be helpful if meningitis is a concern.

## DIFFERENTIAL DIAGNOSIS AND TREATMENT

Using the combination of history, physical examination, and diagnostic studies is detrimental to establish the differential diagnosis of benign axial neck pain, radiculopathy, myelopathy, infection, neoplasm, systemic arthritides, and referred pain. Most axial neck pain is self-limiting and will resolve with appropriate conservative care.[69] Axial neck pain with associated radiculopathy also has a fairly benign course, with 75% of patients having only one recurrence or mild symptoms at 19-year follow-up with conservative treatment.[70] Patients with isolated neck pain and a negative radiographic and laboratory workup are best treated with a multimodal approach. During the acute phase, patients can be treated with a soft collar to reduce inflammation, but the collar should not be worn for more than 2 weeks to avoid deconditioning. Multimodal treatments have been found to be the most effective at treating axial neck pain, including proprioceptive training, exercises with resisted strengthening, muscle relaxants, and NSAIDs.[71-76] Evidence is inconclusive as to the effectiveness of radiofrequency denervation of facet joints, acupuncture, transcutaneous electrical nerve stimulation unit, iontophoresis, EMG biofeedback, or local injections for treatment of axial neck pain.[77-80]

Cervical traction may be prescribed, with a typical regiment of 3.5 to 4.5 kg for 15- to 20-minute sessions with the device at 20 to 25 degrees of flexion. However, this treatment has only shown short-term relief of radicular symptoms.[81] Fluoroscopically guided interlaminar and transforaminal epidural steroids have been shown to be effective at treating lumbar radiculopathy, but not in the cervical spine.[82] Cervical injections carry a higher risk, with complications in up to 16% of patients, including neurologic deficits.[83,84] Given these increased risks with epidural steroid injections in the cervical spine, a more conservative approach should be taken in prescribing this treatment modality. Atlanto-axial facet joint osteoarthritis may be treated successfully with a facet block and NSAIDs. If conservative therapy with NSAIDs fails, a fusion may be indicated.

In addition to degenerative changes to the cervical spine, trauma, and acute disk herniation, more insidious causes of neck pain exist, such as schwannomas, Pancoast's tumor, brachial plexus neuritis, and complex regional pain syndrome. Schwannomas, if intradural, may involve a sensory nerve root, causing dermatomal pain along with a myelopathy or radiculopathy from compression. Pancoast's tumor involving the lung apex may cause caudal cervical nerve root and sympathetic changes in addition to nerve root or brachial plexus compression. Brachial plexus neuritis (Parsonage-Turner syndrome), which is of viral origin, causes severe arm pain followed by weakness and then pain resolution followed by a return of arm strength. This condition may progress to complex regional pain syndrome in a small number of cases associated with diffuse burning pain along with autonomic changes, including discoloration of the skin.

Follow-up and vigilance are in order because a progressive neurologic deficit, segmental instability, or persistent radicular symptoms for at least 6 weeks may be indications for surgical intervention. In a prospective randomized study comparing surgery, physical therapy, or cervical collar use for long-standing cervical radiculopathy, no difference between the three groups was found at 12 months.[85] Cervical myelopathy with very mild deficits can be followed closely; however, the natural course of the illness is long periods of stability with episodes of deterioration. Definitive indications for surgery include the presence of myelopathy for 6 months or longer, progression of signs or symptoms, difficulty walking, or change in bowel or bladder function.

**TABLE 45-6** Rheumatologic Disorders Causing Neck Pain

| • Paget's disease |
| • Acromegaly |
| • Ossification of the posterior longitudinal ligament |
| • Diffuse idiopathic skeletal hyperostosis |

Surgery is directed at decompressing the spinal cord and preventing further deterioration rather than improving neurologic deficits.

Systemic arthritides, infection, and tumors can affect the cervical spine with variable neurologic and constitutional symptoms. RA typically causes atlanto-axial subluxation, atlanto-axial impaction, and subaxial subluxation (Table 45-6). Surgical stabilization is indicated with progressive neurologic deficit, persistent axial neck pain with radiographic evidence of instability, canal diameter of less than or equal to 14 mm (posterior atlanto-dens interval), and odontoid migration of greater than or equal to 5 mm above McGregor's line. In the setting of atlanto-axial subluxation or subaxial subluxation, the involved levels are fused posteriorly and atlanto-axial impaction should be treated with occipitocervical fusion.[15] Patients with rheumatoid disease who have evidence of instability demonstrate radiographic progression over time, but this progression correlates poorly with neurologic outcome.[86] Regardless, these patients require close follow-up given that once myelopathy develops, most patients die within 1 year.[87]

Ankylosing spondylitis commonly affects the cervical spine, resulting in a kyphotic deformity over time with altered biomechanics, which has implications in the setting of trauma. The kyphotic deformity can have significant functional implications as the person's gaze moves toward the floor, making interaction with the surrounding world difficult. Corrective osteotomies are available but carry the risk of neurologic deficit and intra-operative bleeding. However, earlier diagnosis and treatment with tumor necrosis factor blocking agents will help make cervical deformity a thing of the past.[88]

Infection and neoplastic processes both can cause destruction with mechanical or nonmechanical neck pain, constitutional symptoms, and variable neurologic deficit. The goal is similar with eradication of the infection or tumor, decompression if a neurologic deficit exists, and stabilization of the spinal column.

In summary, a careful history, physical examination, and ancillary studies will help one arrive at a fairly narrow differential diagnosis. In the absence of spinal instability, neurologic deficit, or an infectious or neoplastic process, the patient may benefit from conservative treatment with expectant recovery using "tincture of time."

CHAPTER 46

# Shoulder Pain

Scott David Martin • Shivam Upadhyaya • Thomas S. Thornhill

**KEY POINTS**

- **Comprehension of functional anatomy allows diagnosis of most causes of shoulder pain upon clinical examination.**
- **History and clinical examination aided by ancillary tests will usually guide application of the most appropriate treatment for shoulder pain.**
- **The differential diagnosis of shoulder pain includes not only common local disorders (e.g., of tendons and adjacent structures) but also should include consideration of causes arising from distant anatomic sites via referred pain-mediated pathways.**
- **A variety of specific diagnostic tests can greatly aid in the diagnosis of shoulder pain.**
- **Most causes of shoulder pain can be treated with a structured physical therapy program. Successful treatment programs can benefit potential surgical candidates, including those who fail to respond to conservative treatment.**
- **Systemic arthropathies occasionally present with shoulder disease and often involve the shoulder over time. Early assessment in such patients is essential.**

Shoulder pain, which is one of the most common musculoskeletal maladies, may arise from diverse causes. Accurate diagnosis of shoulder pain is made difficult by the unique anatomy and position of the shoulder, which serves as a link between the upper extremity and the thorax. One of the most complex and mobile joints of the body, the shoulder is traversed by muscle, tendon, and bone and is surrounded by major neurovascular structures, all of which may serve as potential sources of local and referred pain.

Determining the source of shoulder pain is essential in order to recommend the proper method of treatment. The examining physician must be able to differentiate the occurrence of shoulder pain caused by intrinsic or local factors, extrinsic or remote factors, or a combination of the two. Intrinsic factors originate from the shoulder girdle and include glenohumeral and periarticular disorders, whereas extrinsic factors occur outside of the shoulder girdle with secondary referral of pain to the shoulder (Table 46-1). An example of an extrinsic factor is left shoulder pain as the initial presentation of coronary artery disease. Hepatic, gallbladder, and splenic disease also may manifest initially as shoulder pain.

Accurate evaluation, diagnosis, and treatment require a thorough understanding of shoulder anatomy, including pain referral patterns. A complete and systematic physical examination is crucial for an accurate diagnosis. During the initial evaluation, care must be taken to discern all possible causes of shoulder pain. The final diagnosis may require repeated office examinations and correlation of diagnostic tests with symptoms, along with response to selective injections. Improvements in diagnostic tests, such as MRI, computed tomography (CT)-arthrography, ultrasonography, and electromyography (EMG), have facilitated early diagnosis of shoulder pain and have provided a better understanding of shoulder disease. This chapter provides practical guidelines for the diagnosis and treatment of painful shoulder disorders that may be encountered in a rheumatology or general practice. A detailed analysis of shoulder problems and information on the treatment of major trauma are beyond the scope of this chapter and have been addressed by other authors.

## ANATOMY AND FUNCTION

Because of the shoulder's complexity, clinicians treating shoulder pain must have an understanding of the structural and functional anatomy of this joint. The shoulder is the most mobile joint of the body, although this mobility is gained at the sacrifice of stability. Only 25% of the humeral head surface has contact with the glenoid at any time. The labrum increases the contact area of the articular surface and confers stability to the joint.[1] Lesions of the labrum may result from instability, and the type of lesion may indicate the type of instability. Labral tears also may be a source of pain from internal derangement of the shoulder.[2] Joint stability is provided by a thin capsule and by the glenohumeral ligaments, which are thickenings of the capsule anteriorly, posteriorly, and inferiorly.[1] Anterior stability is predominantly conferred by the anterior band of the inferior glenohumeral ligament.

The rotator cuff, which provides dynamic stability of the joint, is composed of four musculotendinous units: the supraspinatus, infraspinatus, and teres minor posteriorly, and the subscapularis anteriorly. The shoulder consists of three joints: the acromioclavicular (AC), sternoclavicular, and glenohumeral joints, and two gliding planes—the scapulothoracic and subacromial surfaces.

Figure 46-1 shows the musculoskeletal and topographic localization of pain associated with common shoulder disorders. Figure 46-2 shows the relationship of the three posterior rotator cuff muscles coursing anteriorly underneath the acromion to insert on the greater tuberosity. The subscapularis, the only anterior rotator cuff muscle, inserts on the lesser tuberosity. By understanding the relationship

**TABLE 46-1** Common Causes of Shoulder Pain

| |

between the rotator cuff and the subacromial region, bounded inferiorly by the humeral head and superiorly by the undersurface of the acromion, the clinician can visualize the problems of impingement syndrome and administer an injection into this space with accuracy. Knowledge of the route of the tendon of the long head of the biceps through the bicipital groove and onto the superior aspect of the glenoid helps in understanding bicipital tendinitis. Before attempting to diagnose and treat shoulder pain, the clinician should review in detail one of the many sources describing the structural and functional relationships of the shoulder girdle.[3,4]

# DIAGNOSIS

## Clinical Evaluation of the Shoulder

Accurate diagnosis and successful treatment of a shoulder disorder begin with a thorough history and physical examination. Most of the information needed to make a correct diagnosis can be elicited with basic clinical skills, rather than by relying on expensive and highly technologic investigative aids. Diagnostic tests should be used only to confirm an established diagnosis or to assist in cases with a challenging presentation.

### History

When establishing a diagnosis, it is important to consider the patient's age and chief reason for presenting. The differential diagnosis of shoulder pain in a 70-year-old sedentary person is entirely different from that in a 20-year-old athlete. Did the pain occur slowly over time, or suddenly after a particular event? Gradual onset of pain over the anterolateral or deltoid region that is increased with forward elevation of the shoulder, along with nocturnal pain, suggests impingement with rotator cuff tendinopathy. The presence of significant weakness with pain upon engaging in overhead actions suggests impingement with a rotator cuff tear. Pain and weakness also may be noted upon reaching behind the back with the shoulder in extension and external rotation, as when reaching into the back seat of a car. Initiating factors relative to the onset of symptoms should be elicited, and any history of shoulder pain or trauma should be carefully documented.

Pain intensity, character, location, and periodicity and aggravating or alleviating factors should be assessed. Pain should be graded on a visual analog scale of 0 to 10, with 0 indicating no pain and 10 indicating the worst pain the patient has ever experienced. Another indication of the severity of pain is disruption of sleep; the patient should be asked if the pain prevents sleep or awakens the patient and if he or she can lie on the affected shoulder. The patient also should be asked if the pain is sharp or dull. Sharp, burning pain over the top of the shoulder indicates a neurogenic origin, whereas a dull, aching pain over the lateral deltoid suggests rotator cuff disease with impingement. The location or distribution of the pain should be identified: Is it local around the shoulder girdle, or does the pain radiate down the arm? Is concomitant sensory loss or weakness present? Periodicity of the pain as constant or intermittent should be determined, along with factors that aggravate or alleviate the pain. Pain caused by rotator cuff tendinopathy usually is exacerbated by repetitive activities that involve the elbow away from the side of the body.

Any history of neck pain should be considered, along with a history of radicular pain. Radicular-type pain frequently extends below the elbow and is associated with sensory loss and weakness. Pain located in the paracervical region may indicate a cervical origin, or it can be localized to the trapezius. Trapezial pain often is associated with shoulder pain and results from the patient trying to favor the shoulder. Assuming a military brace position may produce fatigue, spasm, and trigger points of the trapezius.

Any pertinent medical history, such as a history of malignancy, should be considered. Neurologic, visceral, and vascular disease can produce referred pain to the shoulder and should always be considered, especially in a patient with painless range of motion.

### Physical Examination

Proper physical examination of the shoulder includes close inspection of the shoulder girdle from the front and back. The evaluation is started by standing behind the patient, who has both shoulders exposed. The normal shoulder is always inspected and compared with the injured shoulder. Examination can be performed with the patient in the sitting or standing position. Contour and symmetry are observed and compared between shoulders, and any atrophy or asymmetry in shoulder position or level is assessed.

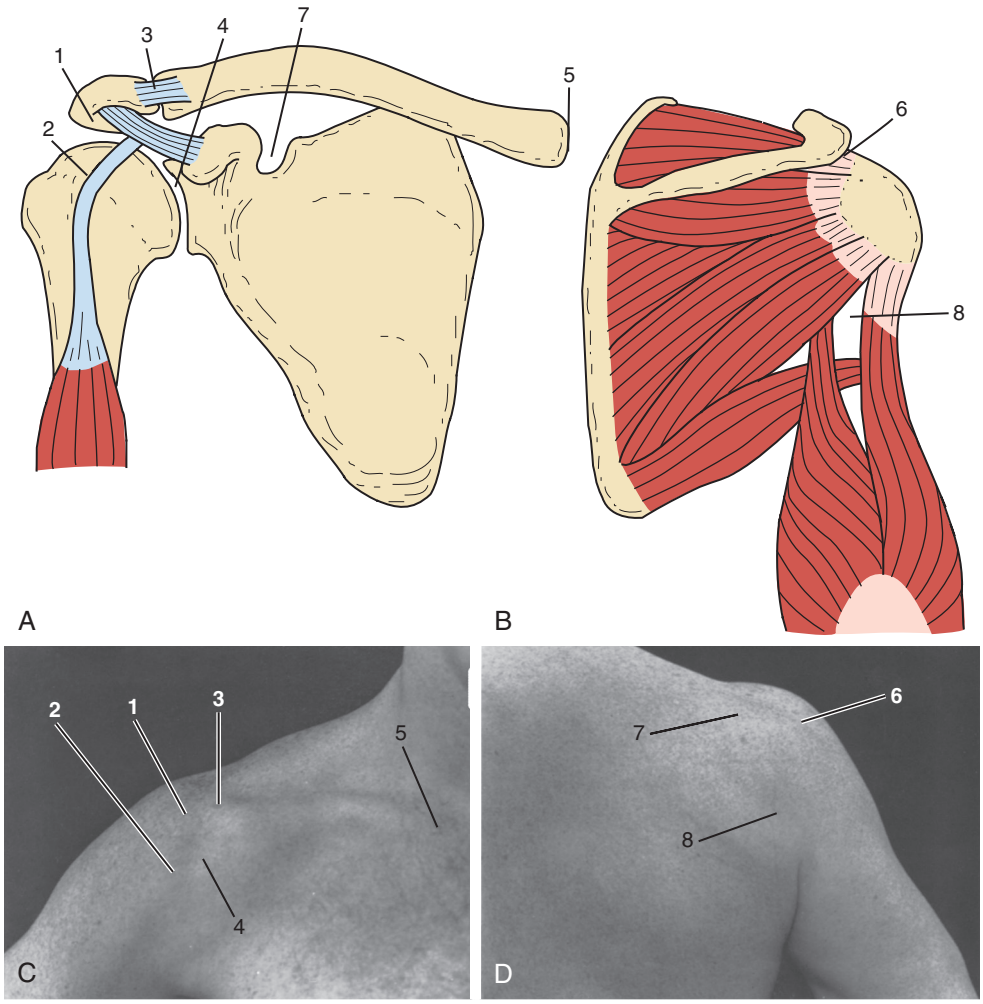

**Figure 46-1** Musculoskeletal (**A** and **B**) and topographic (**C** and **D**) areas localizing pain and tenderness associated with specific shoulder problems. *1,* Subacromial space (rotator cuff tendinitis/impingement syndrome, calcific tendinitis, and rotator cuff tear). *2,* Bicipital groove (bicipital tendinitis, biceps tendon subluxation, and tear). *3,* Acromioclavicular joint. *4,* Anterior glenohumeral joint (glenohumeral arthritis, osteonecrosis, glenoid labrum tears, and adhesive capsulitis). *5,* Sternoclavicular joint. *6,* Posterior edge of acromion (rotator cuff tendinitis, calcific tendinitis, and rotator cuff tear). *7,* Suprascapular notch (suprascapular nerve entrapment). *8,* Quadrilateral space (axillary nerve entrapment). These areas of pain and tenderness frequently overlap.

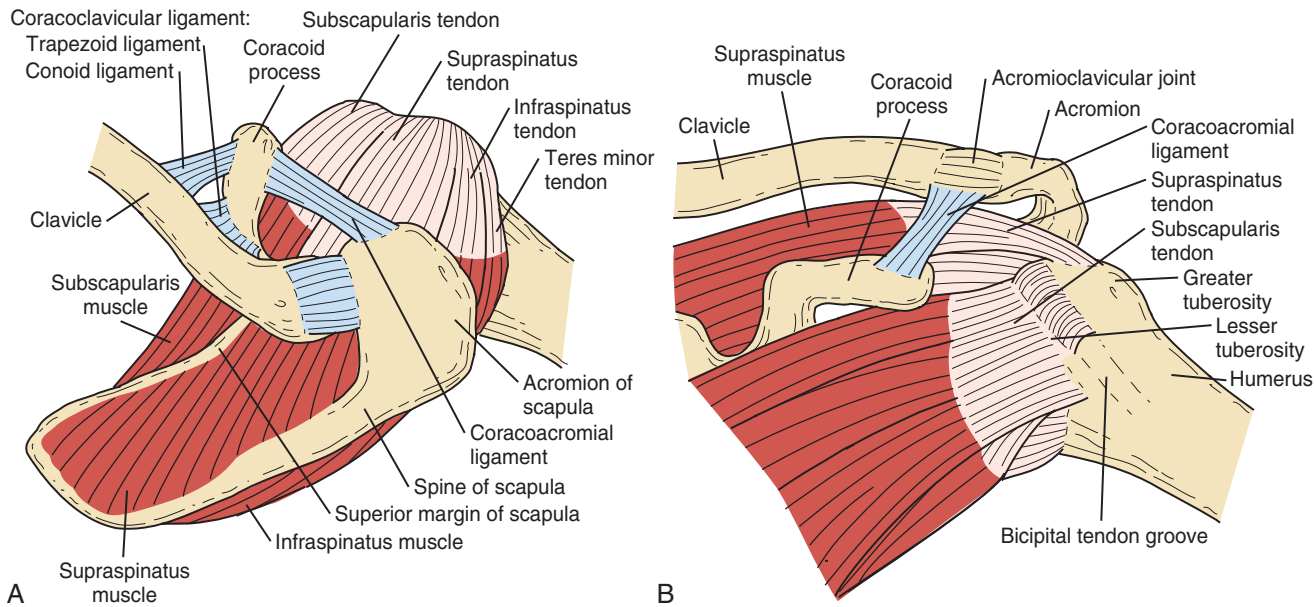

**Figure 46-2** **A,** Superior view of the rotator cuff musculature as it courses anteriorly underneath the coracoacromial arch to insert on the greater tuberosity. **B,** Anterior view of the shoulder reveals the subscapularis, which is the only anterior rotator cuff muscle inserting on the lesser tuberosity. It internally rotates the humerus and provides dynamic anterior stability to the shoulder. *(From* the Ciba Collection of Medical Illustrations, *Volume 8, Part I. Netter Illustration from* www.netterimages.com. *Copyright Elsevier Inc. All rights reserved.)*

Spinatus muscle atrophy may result from disuse, chronic cuff tear, or suprascapular or brachial neuropathy.[5] If scapular winging is evident, the patient should be asked to perform a wall push-up, which accentuates winging.

Range of motion should be carefully recorded, along with notation of any absence of rhythmic shoulder motion or excessive scapulothoracic motion that may compensate for the lack of glenohumeral motion. Internal rotation of the shoulder is checked by having the patient reach behind his or her back with the thumb while the examiner notices the vertebral level. Loss of internal rotation is seen early with shoulder pain and usually indicates some tightness of the posterior shoulder capsule. The biceps tendon is palpated, along with the coracoid, lesser, and greater tuberosities and the posterior cuff, and any tenderness is gauged (Figure 46-3A). Tenderness upon palpation of the long head of the biceps is frequently associated with rotator cuff tendinopathy and tenderness of the greater tuberosity. Any spasm or tenderness of the trapezius or levator scapulae may be associated with rotator cuff or cervical spine disease. Cervical range of motion is evaluated, and the paracervical muscles are palpated. Paracervical tenderness and limited range of motion of the neck may indicate cervical spondylosis or neurogenic disease. A Spurling test is performed by flexing the neck laterally while applying axial compression to the skull. Pain that radiates to the ipsilateral shoulder is considered a positive test result and indicates radiculopathy.

To elicit the impingement sign, the shoulder is elevated passively in forward flexion while the scapula is depressed with the opposite hand, forcing the greater tuberosity against the anterior acromion and producing pain in cases of impingement (Figure 46-3B).[6] This maneuver also may be painful in the presence of conditions such as adhesive capsulitis, glenohumeral and AC arthritis, glenohumeral instability, and calcific tendinitis. A dynamic impingement test, known as the circumduction-adduction shoulder maneuver (also called the Clancy test), is 95% sensitive and 95% specific for diagnosing rotator cuff tendinopathy,

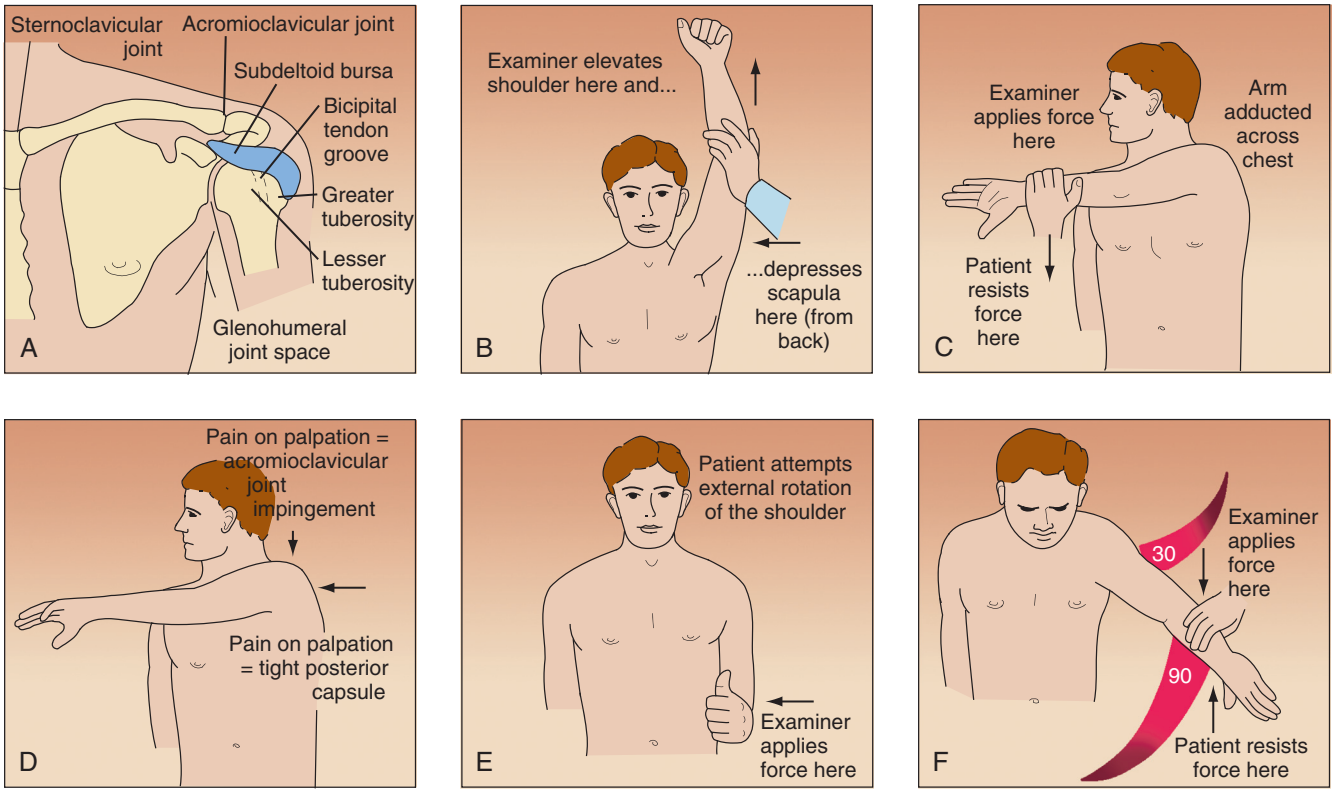

**Figure 46-3** **A,** Tenderness upon palpation of trigger points may help localize the site of disease. Tenderness upon palpation of the long head of the biceps and greater tuberosity suggests impingement with possible cuff tendinopathy. **B,** To elicit the impingement sign, the shoulder is elevated in forward flexion while the scapula is depressed with the opposite hand, forcing the greater tuberosity and the rotator cuff against the anterior acromion and producing pain when impingement exists. Relief of pain after injection of local anesthetics (i.e., the impingement test) provides additional evidence of subacromial disease. **C,** The Clancy test is performed with the patient standing and with the head turned toward the contralateral shoulder. The affected shoulder is circumducted and adducted across the body to shoulder level, keeping the elbow in extension with the arm internally rotated with the thumb pointed toward the floor. In this position, the patient is asked to resist maximally as a uniform downward force is applied to the extended arm by the examiner. Production of pain or weakness localized to the anterior lateral portion of the shoulder is considered a positive test result. **D,** The test is performed by forward flexion of the arm at 90 degrees and subsequent cross-chest adduction of the arm. Pain localized to the acromioclavicular joint is considered a positive test result. **E,** The test is performed with the patient's elbow flexed at 90 degrees and held at the patient's side by the examiner. The patient is asked to attempt external rotation of the shoulder from a neutral position (0 degrees of adduction) as the examiner applies resistance to the forearm. Strength is compared with that of the contralateral arm. **F,** Abduction strength testing is performed with the patient's shoulder in 30 degrees of forward flexion and 90 degrees of abduction and with the thumb pointed toward the floor. The patient is asked to resist as the examiner exerts a downward force on the abducted arm. Strength is compared with the contralateral shoulder. *(From Martin TL, Martin SD: Rotator cuff tendinopathy.* Hosp Med *12:23–31, 1998.)*

including partial tears.[7] The test is performed with the patient in the standing position, with the head turned to the contralateral shoulder. The affected shoulder is circumducted and adducted across the body to shoulder level while the elbow is kept in extension, the shoulder is in internal rotation, and the thumb is pointing toward the floor (Figure 46-3C). In this position, the patient is instructed to resist maximally as a uniform downward force is applied to the extended arm by the examiner. The test result is considered positive if pain or weakness is elicited during the maneuver, with pain localized to the anterolateral aspect of the shoulder. A strong positive correlation of pain and weakness is noted with a complete cuff tear.[7]

The sternoclavicular and AC joints should be observed for prominences and palpated for stability and tenderness. Many patients with impingement have tenderness upon direct downward palpation of the AC joint as a result of impingement on the cuff from undersurface osteophytes of the distal clavicle.[3,5]

AC joint tenderness also may result from primary AC joint arthrosis and should be differentiated by physical examination, including the cross-chest adduction test and O'Brien's test.[8] Radiographic evidence of AC joint arthrosis is common in patients older than 40 years, but this condition usually is not painful.[9]

The cross-chest adduction test or the horizontal adduction test is performed by forward flexing the shoulder 90 degrees with subsequent cross-chest adduction of the arm (Figure 46-3D). Pain localized to the AC joint is considered a positive test result. If pain occurs posteriorly over the shoulder, a tight posterior capsule with impingement is suspected. O'Brien's test is performed by forward flexing the arm 90 degrees and adducting the arm 10 degrees out of the sagittal plane of the body. The first part of the test is performed with the hand maximally pronated with the thumb pointed down. In this position, the patient is asked to resist as the examiner applies a downward force on the arm. If the test elicits pain, the patient is asked if the pain is on top of the shoulder or deep inside. Pain localized to the top of the shoulder indicates AC joint pain, and pain deep inside the shoulder indicates a superior labrum anterior posterior (SLAP) lesion. In the second part of the test, the patient is asked to supinate the hand maximally, while the examiner applies a downward force to the arm. If the patient notices significantly less pain, the test result is positive for a SLAP lesion. If the pain is unchanged and is located on top of the shoulder, the test result is positive for AC joint disease.[8]

If the cause of AC joint tenderness is still in question, a lidocaine injection should be administered. The clinician should carefully avoid injecting the lidocaine into the subacromial space by advancing the needle too far inferiorly through the AC joint, which can lead to a false interpretation. Painful degenerative changes of the AC joint may exist concomitantly with subacromial impingement and should be evaluated thoroughly when surgical treatment (i.e., distal clavicle excision) is being considered.[10]

In patients with pain out of proportion to objective findings, other causes of shoulder pain should be sought, including calcific tendinitis, infection, reflex sympathetic dystrophy, and fracture. Patients with significant wasting of the supraspinatus and infraspinatus muscles and posterior shoulder pain, especially younger patients, may have suprascapular neuropathy or brachial neuropathy (Parsonage-Turner syndrome).[5,11]

Patients with chronic cuff disease frequently have variable disuse atrophy of the supraspinatus and infraspinatus fossae. In cases of chronic massive cuff tears, atrophy and weakness can be severe. Strength testing of external rotation should be performed with the elbow at the side and supported by the examiner; the patient is asked to attempt external rotation of the shoulder from a neutral position (0 degrees of adduction) while the examiner applies resistance (Figure 46-3E).[12] Weakness in this position may suggest a tear of the infraspinatus tendon. Abduction strength testing against resistance is performed with the shoulder in 30 degrees of forward flexion and 90 degrees of abduction and with the thumb pointed toward the floor (Figure 46-3F).[13,14] Weakness in this position may suggest a tear of the supraspinatus tendon. A lift-off test should be performed with the shoulder in internal rotation; the patient is asked to try to hold his or her hand away from the back. Inability to do so indicates a subscapularis tear.

If impingement is suspected after a thorough physical examination, an impingement test should be performed with injection of 5 mL of a local anesthetic into the subacromial space.[15,16] Before the test is performed, the patient is asked to grade the pain during the impingement signs on a visual analog scale of 0 to 10, with 0 equal to no pain and 10 equal to the most severe pain the patient has ever experienced. The injection may be performed anteriorly, laterally, or posteriorly, depending on the physician's preference. Ten minutes after injection of a local anesthetic into the subacromial space, the patient should be re-examined and asked to grade the pain again on the same visual analog scale. A 50% or greater reduction in pain is thought to be a positive test result for impingement; otherwise, an alternative cause of shoulder pain should be sought, or inadequate placement of the anesthetic should be suspected. If the AC joint is thought to be contributing to the shoulder pain, 1 to 2 mL of a local anesthetic should be injected into the joint, and the shoulder should be re-examined. When subacromial impingement and the AC joint are thought to be contributing to shoulder pain, serial injections during separate office visits may be required to evaluate the shoulder while minimizing discomfort to the patient.[9]

In cases of suspected bicipital tendinitis, Speed's test is performed by having the patient flex the shoulder and extend the elbow while a downward force is applied to the arm. The production of pain over the long head of the biceps is a positive test result and suggests bicipital tendinitis.

Upper extremity strength testing should be performed and compared with the contralateral side so that any atrophy is detected. Grip strength is checked, and the hands are examined carefully for evidence of intrinsic atrophy. The biceps (C5), triceps (C7), and brachioradialis (C6) reflexes are checked for symmetry and briskness.

Light touch sensory testing should be conducted, and the dermatomal distribution of any deficits that may suggest that cervical radiculopathy should be identified. The cervical, supraclavicular, axillary, and epitrochlear regions should be palpated for enlarged lymph nodes, which may suggest malignancy.

## Imaging

### Radiographic Assessment

For nontraumatic painful shoulder evaluation, standard radiographic profiles are used. An impingement series should be obtained, which includes anteroposterior views with a 30-degree caudal tilt (Rockwood view), an outlet view (scapular Y with a 10- to 15-degree caudal tilt), and an axillary view. Internal and external rotational views may be obtained if calcific tendinitis or instability is suspected. The Rockwood view can reveal any osteophytes off the anterior acromion and AC joint.[17] In cases of traumatic injury, a trauma series is obtained that includes a true anteroposterior view, a scapular Y view, and an axillary view. The axillary view is useful in assessing posterior or anterior subluxation of the humeral head. Additional views, such as the West Point view, which evaluates the glenoid for evidence of a bony Bankart lesion, or the Styker notch view, which assesses the humeral head for a Hill-Sachs lesion, may be obtained to assist in the evaluation if the diagnosis of instability is in doubt. Secondary impingement-type rotator cuff tendinitis may be caused by increased anterior translation with subluxation of the humeral head. In such cases, an axillary view or fluoroscopy can help show the subluxation.[18,19]

When AC joint disease is suspected, a 10-degree, cephalic tilt view of the AC joint at 50% penetrance, as described by Zanca,[20] should be obtained (Figure 46-4). Stress views of the AC joint may be obtained by strapping 5- to 10-lb weights to the patient's forearms and determining AC separation. Comparing the coracoclavicular distance of both shoulders may be helpful. When clinically indicated, cervical spine radiographs should be obtained to exclude cervical spondylosis as a cause of shoulder pain.

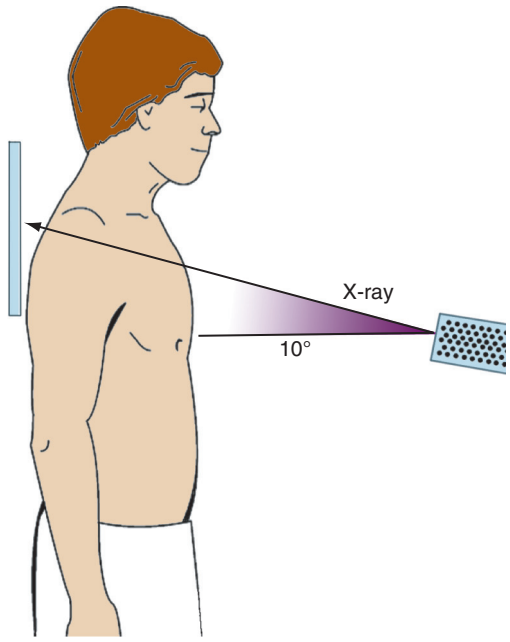

**Figure 46-4** The Zanca view of the acromioclavicular joint is obtained with a 10-degree cephalic tilt and 50% penetrance. *(From Rockwood CA Jr, Young DC: Disorders of the acromioclavicular joint. In Rockwood CA Jr, Matsen TA III, editors:* The shoulder. *Philadelphia, 1985, WB Saunders, pp 413–476.)*

### Scintigraphy

Technetium 99m (Tc 99m) methyl diphosphonate (MDP) or gallium may be of diagnostic help in evaluating skeletal lesions in the area of the shoulder joint. Bone scans generally are not helpful in the diagnosis of non-neoplastic or noninfectious shoulder disease.

Scintigraphy may have a role in identifying patients with complete rotator cuff tears that evolved to cuff-tear arthropathy. This distinction is important because patients with complete rotator cuff tears may do well, whereas patients who experience progressive changes of cuff-tear arthropathy have progressive arthritis, pain, and significant functional impairment. Synovitis or calcium pyrophosphate deposition disease may be an important factor in the pathogenesis of cuff-tear arthropathy. In such cases, scintigraphy may show the increased blood flow and blood pooling associated with chronic synovitis.

### Arthrography

Double-contrast arthrotomography (DCAT) can be used to evaluate problems of the rotator cuff, glenoid labrum, biceps tendon, and shoulder capsule.[21-24] Figure 46-5 shows normal DCAT of the shoulder. Rotator cuff tears can be shown by single-contrast or double-contrast studies. Proponents of double-contrast arthrography believe that the extent of the tear, the preferred surgical approach, and the quality of the rotator cuff tissue are best determined by double-contrast studies.[21-26] Arthrography without MRI or CT can be misleading and may result in underestimation of the extent of a rotator cuff tear. Multidetector CT can enhance the accuracy of diagnosing labral and rotator cuff tears, especially in patients for whom MRI is not possible (Figure 46-6).

Tears of the glenoid labrum without shoulder dislocation are sources of anterior shoulder pain in athletes.[2] Glenoid

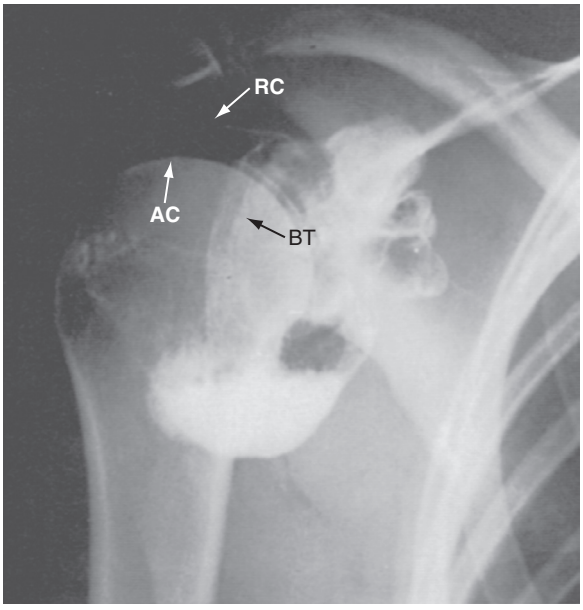

**Figure 46-5** Normal double-contrast arthrography shows the inferior edge of the rotator cuff (RC) as it courses through the subacromial space to the greater tuberosity, the tendon of the long head of the biceps (BT), and the articular cartilage of the humeral head (AC).

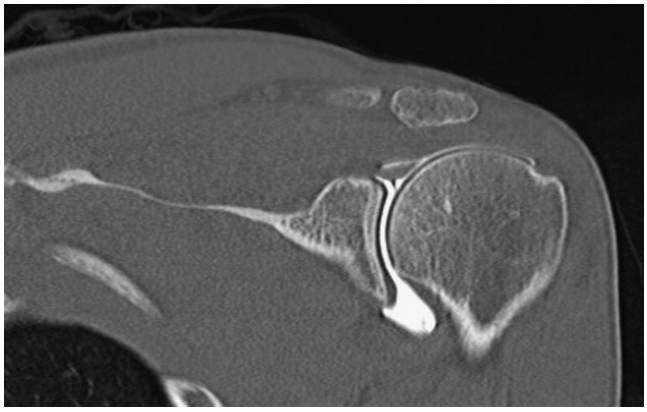

**Figure 46-6** Multidetector computed tomography reveals a superior labral tear of the shoulder.

**Figure 46-7** Double-contrast arthrotomography shows a tear of the anterior-inferior portion of the glenoid labrum *(arrow)*.

labrum tears (Figure 46-7), with or without associated glenohumeral subluxation, frequently can be identified by DCAT.[24,25] Kneisl and colleagues[27] described 55 patients who underwent DCAT followed by diagnostic shoulder arthroscopy. DCAT predicted the arthroscopic findings in 76% of anterior labrum studies and 96% of posterior labrum studies. This test was 100% sensitive and 94% specific in diagnosing complete rotator cuff tears. Partial rotator cuff tears identified at arthroscopy were missed in 83% of patients who underwent DCAT. Investigators believed that DCAT was more effective in diagnosing intra-articular and cuff disease in cases of instability than when pain alone was the presenting diagnosis.[27]

Shoulder arthrography can confirm a diagnosis of adhesive capsulitis by showing a contracted capsule with an obliterated axillary recess (Figure 46-8). The use of subacromial bursography has been beneficial in visualizing the outer surface of the rotator cuff and the subacromial space in cases of impingement.[28,29] Fukuda and associates[30] reported

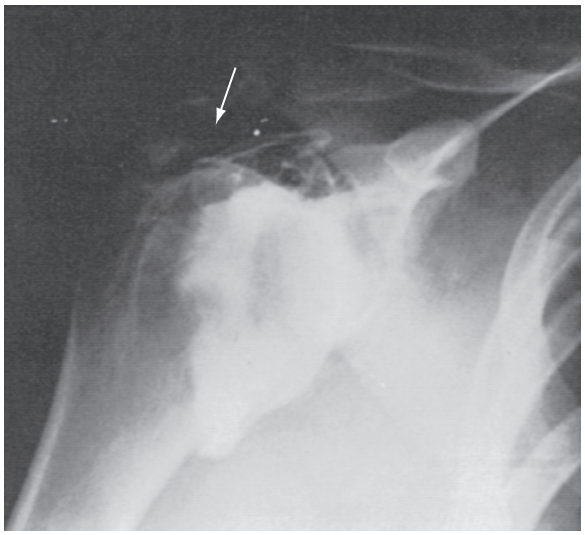

**Figure 46-8** Double-contrast arthrography of a patient with calcific tendinitis *(arrow)* and adhesive capsulitis. Notice the contracted capsule with diminution of the synovial space and obliteration of the axillary recess.

a small series of younger patients (average age, 41.8 years) who underwent subacromial bursography after a negative glenohumeral arthrographic result. These patients showed pooling of contrast medium on the bursal side of a tear, which was confirmed at the time of surgery. Subacromial bursography is not routinely used diagnostically, and in our opinion, it is of little value in planning surgical procedures.

## Computed Tomography

CT is helpful in evaluating the musculoskeletal system, and CT combined with contrast arthrography (CT-arthrography) has become a major diagnostic tool for the evaluation of glenoid labrum tears, loose bodies, and chondral lesions (Figure 46-9). Rafii and co-workers[31] reported using CT-arthrography in an evaluation of shoulder derangement and found 95% accuracy of CT-arthrography for investigating lesions of the labrum and articular surface.[34] More recently, multidetector CT-arthrography scans have been used to evaluate partial cuff tears (Figure 46-10A), cystic lesions (Figure 46-10B), and calcific tendinopathy (Figure 46-10C).

## Ultrasonography

Technologic improvements in ultrasound equipment have led to improved ultrasound study of the rotor cuff. The technique is noninvasive and rapid and involves no radiation exposure.[27-29,32] The cuff is examined in the horizontal and transverse planes with the arm in different positions to allow visualization of various areas of the cuff. These techniques generally provide visualization of the distal cuff, where most rotator cuff tears are located. Figure 46-11 shows normal and abnormal ultrasound images of the rotator cuff in longitudinal and transverse planes.

Several studies report high sensitivity and specificity for the diagnosis of a rotator cuff tear by ultrasound.[29-32] The

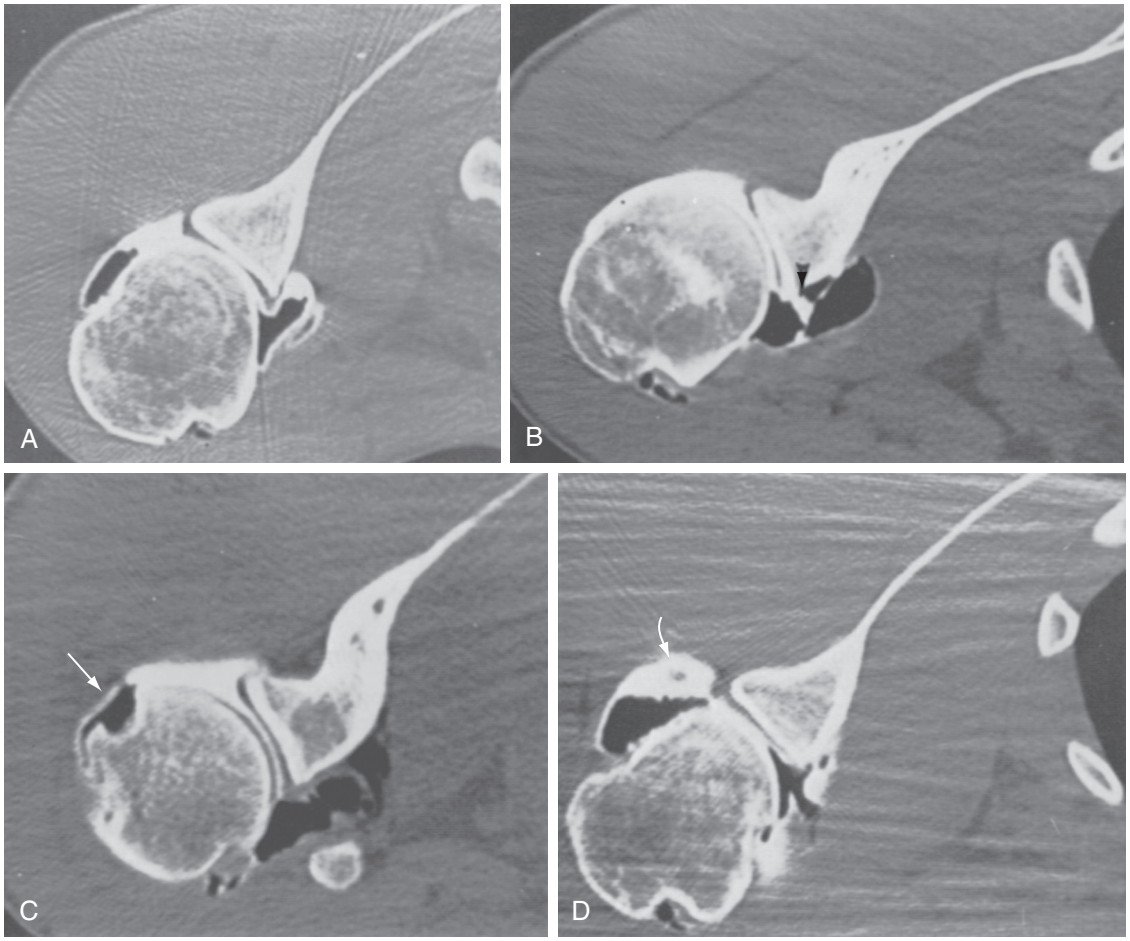

**Figure 46-9** Computed tomography–arthrography of the shoulder. **A,** Normal findings. **B,** A tear of the anterior glenoid labrum. **C,** A large defect of the articular surface of the posterior portion of the humeral head (Hill-Sachs lesion) *(arrow)*. **D,** A loose body in the posterior recess *(arrow)*.

specificity and sensitivity of the procedure are reported to be greater than 90% as determined by arthrographic and surgical correlations.[31,32] This technique has also been used for the post-operative evaluation of a rotator cuff repair and for evaluation of abnormalities of the biceps tendon.[33-37]

Gardelin and Perin[38] reported ultrasound to be 96% sensitive in determining rotator cuff and biceps tendon disease. Mack and associates[33] found ultrasound to be valuable in evaluating post-operative patients with recurrent shoulder symptoms. In a prospective study, Hodler and colleagues[36] compared ultrasound with MRI and arthrography in evaluating rotator cuff lesions in 24 shoulders. Ultrasound identified 14 of 15 torn cuffs, MRI identified 10 of 15, and arthrography identified 15 of 15.[36] Ultrasound identified 7 of 9 intact rotator cuffs, whereas MRI was accurate in 8 of 9 intact cuffs.[36] Vestring and colleagues[39] found ultrasound to be as accurate as MRI in the diagnosis of humeral head defects and joint effusions but inferior to MRI in the diagnosis of labrum lesions, rotator cuff lesions, subacromial spurs, and synovial inflammatory disease. In the hands of an experienced sonographer, ultrasound may be the most cost-effective test for the initial evaluation of a rotator cuff injury, but most surgeons require CT-arthrography or MRI confirmation before beginning surgical exploration.[33,36,38-40]

### Magnetic Resonance Imaging

MRI has been used to diagnose partial-thickness and full-thickness rotator cuff tears, biceps tendon tears, impingement of the rotator cuff, synovitis, articular cartilage damage, and labral disease associated with glenohumeral instability.[41-43] In rheumatoid arthritis (RA), MRI is reported to be more sensitive than plain radiographs in determining soft tissue abnormalities and osseous abnormalities of the glenoid and humeral head.[44]

One of the most valuable diagnostic uses of MRI is in rotator cuff disease. Morrison and Offstein[45] studied 100 patients with chronic subacromial impingement syndrome using arthrography and MRI. MRI was 100% sensitive but only 88% specific in confirming arthrography-proven rotator cuff tears. Nelson and associates[46] studied 21 patients with shoulder pain and found MRI to be more accurate than CT-arthrography or ultrasound in identifying partial-thickness cuff tears. These investigators also reported MRI to be as accurate as CT-arthrography in the diagnosis of abnormalities of the glenoid labrum.[46]

Characteristic MRI findings in persons with rotator cuff tears include a hypointense gap within the supraspinatus muscle tendon complex on T1-weighted films, absence of a

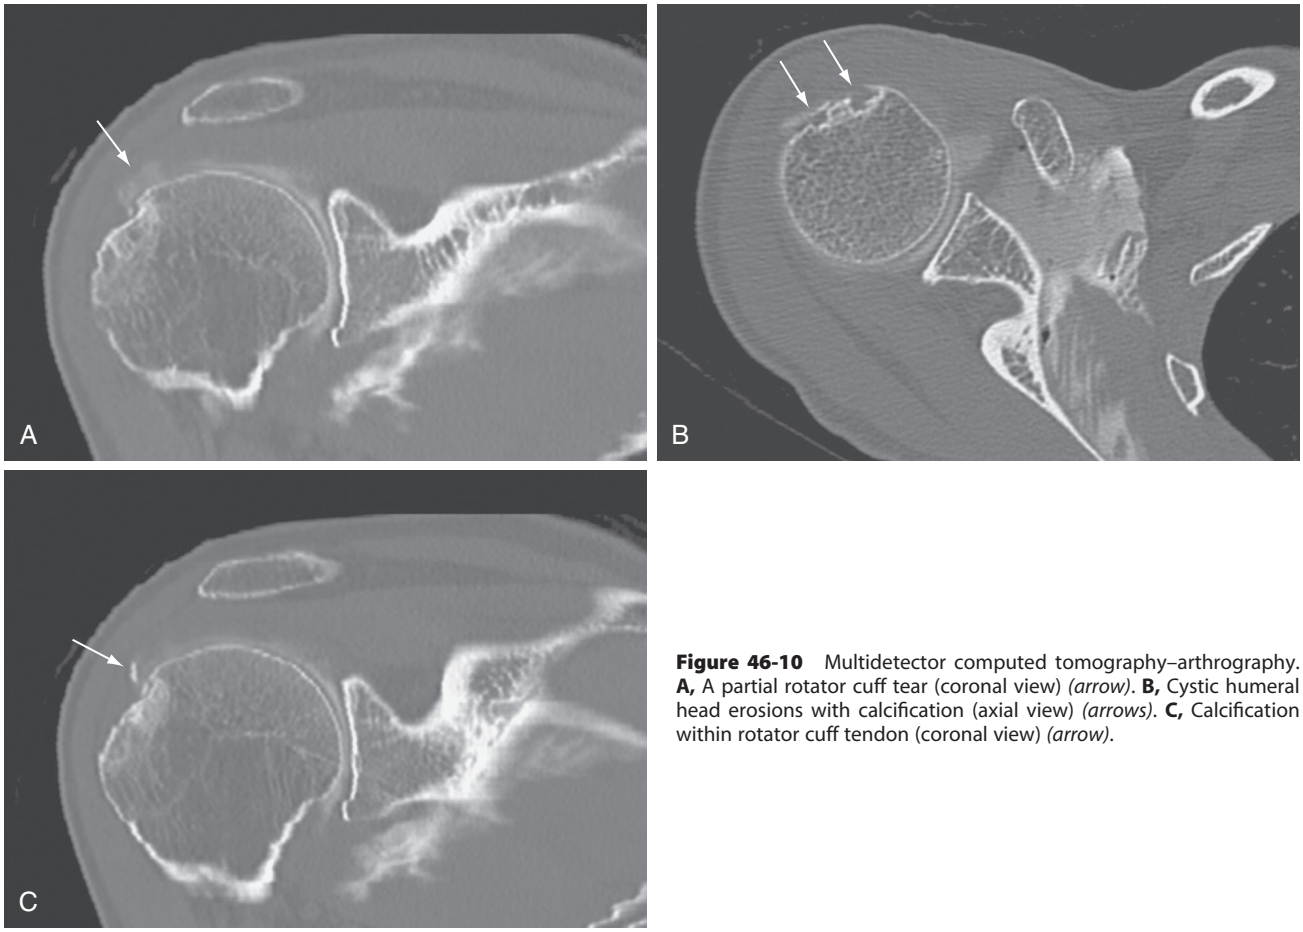

**Figure 46-10** Multidetector computed tomography–arthrography. **A,** A partial rotator cuff tear (coronal view) *(arrow)*. **B,** Cystic humeral head erosions with calcification (axial view) *(arrows)*. **C,** Calcification within rotator cuff tendon (coronal view) *(arrow)*.

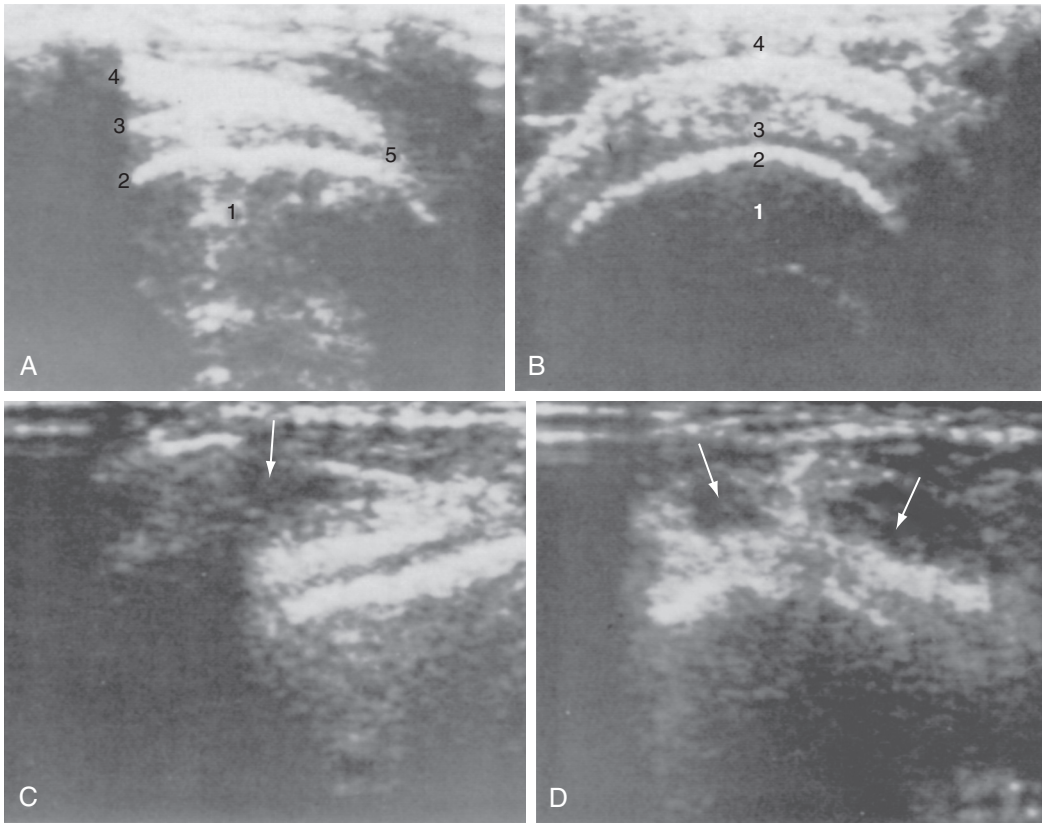

**Figure 46-11** **A,** A normal longitudinal view of the rotator cuff by ultrasound shows the humeral head *(1),* the superior articular surface *(2),* the rotator cuff *(3),* the deltoid tendon *(4),* and tapering of the cuff to its insertion on the greater tuberosity *(5).* **B,** A transverse view of a normal intact rotator cuff covering the humeral head. **C,** A rotator cuff tear showing a hypoechoic area *(arrow)* on a longitudinal view. **D,** A rotator cuff tear showing a hypoechoic area *(arrows)* on a transverse view.

demonstrable supraspinatus tendon with narrowing of the subacromial space, and an increased signal within the supraspinatus tendon on T2-weighted images.[47] Seeger and colleagues,[48] who reported the results of 170 MRI studies, found that T1-weighted images were highly sensitive for identifying abnormalities within the supraspinatus tendon but that T2-weighted images were required to differentiate tendinitis from a small supraspinatus tendon tear. However, large full-thickness tears could be identified on T1- and T2-weighted images. Figure 46-12 depicts common shoulder disease as seen by MRI. Compared with scintigraphy, MRI is almost as sensitive and more specific in the diagnosis of osteonecrosis and neoplastic lesions in the shoulder area.

## Arthroscopy

The use of arthroscopy for the diagnosis of shoulder disease increased in the 1980s, in part because of its accuracy, which was far greater than that of clinical examination and better than the accuracy of other diagnostic modalities of the time. With technologic advances in fiberoptics, video output, and arthroscopic instrumentation, the use of arthroscopy to diagnose and treat shoulder problems exponentially increased to include procedures previously used only for open techniques.[49]

Compared with DCAT, arthroscopy is more accurate in the diagnosis of intra-articular lesions associated with a

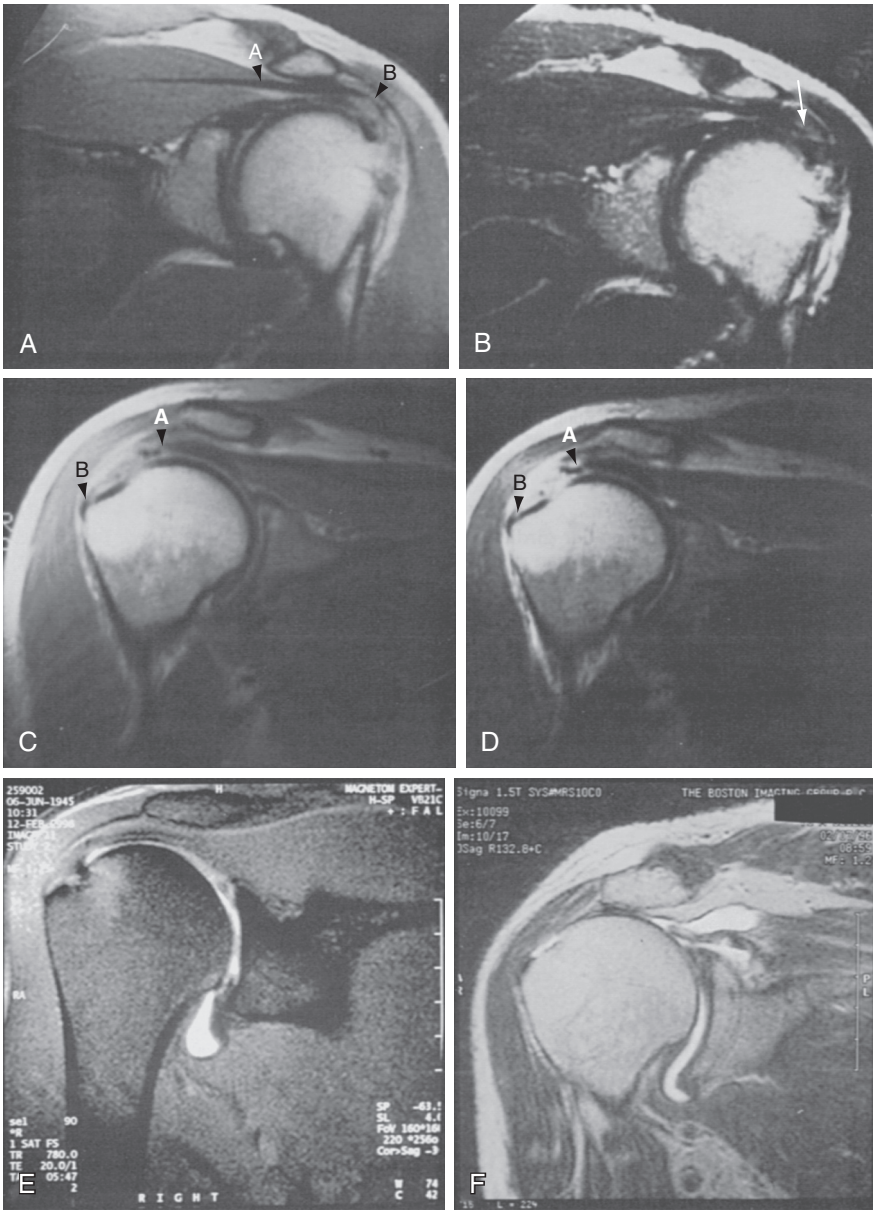

**Figure 46-12** **A,** An MRI proton density–weighted coronal view shows the supraspinatus tendon as a black band *(A)* that has an increased signal as it nears insertion on the greater tuberosity *(B)*. **B,** A similar view with a T2-weighted image shows increased signal as gray *(arrow),* indicating a partial-thickness tear or tendinitis. **C,** MRI proton density–weighted coronal view shows abrupt end of supraspinatus tendon as it courses right to left *(A)*. From A to B is an area of increased signal followed by a short portion of tendon *(B)* inserting at the greater tuberosity. **D,** A similar view on a T2-weighted image shows increased signal as white (fluid density), indicating fluid in the gap of a complete rotator cuff tear. **E,** MR arthrography shows a normal rotator cuff. **F,** MR arthrography shows a chronic cuff tear with retraction.

painful shoulder.[27] An additional benefit is that arthroscopy can be used to diagnose and treat shoulder problems of the glenohumeral joint and the subacromial region. With increased accuracy of MRI-arthrography in detecting partial cuff tears and labral lesions, diagnostic shoulder arthroscopy has become less common in the absence of clear indications and specific treatment plans. In combination with a detailed history and physical examination, and along with examination under the effects of anesthesia, shoulder arthroscopy has been helpful in the diagnosis of chronic instability patterns of the glenohumeral joint.[49-52]

The indications and usefulness of shoulder arthroscopy in the treatment of common pathologic conditions have continued to increase as the technology improves and as understanding of the pathophysiology of shoulder problems grows. Shoulder arthroscopy has been used routinely to confirm and treat SLAP lesions, labral tears, partial cuff tears, refractory adhesive capsulitis, partial biceps tendon tears, and multidirectional instability. Other conditions that are routinely treated arthroscopically include rotator cuff tears, glenohumeral instability, AC joint disease, loose bodies, sepsis, osteochondritis dissecans, synovitis, chondral lesions, subacromial impingement, and calcific tendinitis.[2,10,49,52]

## Electromyography and Nerve Conduction Velocity Studies

EMG and nerve conduction velocity studies can help differentiate shoulder pain from pain of neurogenic origin. They also may be beneficial in determining the localization of neurogenic pain to a particular cervical root, the brachial plexus, or a peripheral nerve.[53,54]

## Injection

Injection of local anesthetics and glucocorticoids is a useful technique for the diagnosis and treatment of shoulder pain.[55] The physician must have a thorough understanding of the anatomy of the shoulder girdle and a presumptive diagnosis to direct the injection properly. Injection of referred pain areas may be misleading. In a patient with lateral arm pain resulting from deltoid bursal involvement from calcific tendinitis of the supraspinatus tendon, the injection should be directed to the subacromial space, rather than the area of referred pain in the deltoid muscle. It is often better to use a posterior or lateral subacromial approach when performing an injection for rotator cuff tendinitis in a patient with anterior impingement symptoms because it is easier to enter the subacromial region posteriorly or laterally, and this approach is less traumatic for contracted anterior structures.

The instillation of rapidly acting local anesthetics can be beneficial in determining the source of shoulder pain. Obliteration of pain by injection of a local anesthetic along the bicipital groove can confirm a diagnosis of bicipital tendinitis. The use of local anesthetics is less helpful when the subacromial space is injected because of its extensive communication with the remainder of the shoulder girdle, but relief of symptoms after such an injection can exclude pain from conditions such as cervical radiculopathy or entrapment neuropathy.

**TABLE 46-2** Relative Costs of Shoulder Diagnostic Procedures in 2014

| Procedure | Initial Fee (USD) | Technical Fee (USD) | Interpretation Fee (USD) |
|---|---|---|---|
| **Medicare B Fee Schedule** | | | |
| Initial office visit (30 min) | 108.18 | | |
| Plain radiography (3 views) | | 91.36 | 29.36 |
| Arthrography | | 340.49 | 72.78 |
| MRI | | 492.63 | 86.33 |
| Computed tomography | | 287.65 | 61.79 |
| **Institutional Charges** | | | |
| Initial office visit (30 min) | 394.00 | | |
| Plain radiography (3 views) | | 436.00 | 35.00 |
| Arthrography | | 625.00 | 302.00 |
| MRI | | 4785.00 | 350.00 |
| Computed tomography | | 2184.00 | 181.00 |

USD, U.S. dollars.

## Potential Diagnostic Tests

Table 46-2 lists reimbursement and charges for various shoulder diagnostic tests based on 2014 Medicare fee schedules and 2014 charges at a single institution. The choice of a specific test depends on its sensitivity, specificity, and cost-benefit analysis. History and physical examination are the most important factors in establishing diagnosis of the painful shoulder. Plain radiographs (three views) should be the first radiographic tests performed. Although they are not as sensitive as the more sophisticated tests, plain radiographs can identify arthritic change, calcific tendinitis, established osteonecrosis, and most neoplasms.

If intra-articular disease (e.g., a labrum tear, capsular tear, loose body, or chondral defect) is suspected, MRI-arthrography is preferable to CT-arthrography. In diagnosing acute rotator cuff tears in a younger patient, ultrasound is the most cost-effective test to confirm a clinical suspicion. In cases of impingement syndrome, MRI is sensitive, but it is difficult to differentiate tendinitis, partial tears, and small complete tears without MRI-arthrography. Orthopedic surgeons prefer use of MRI-arthrography for verification of labral tears or partial rotator cuff tears. In the case of a suspected full-thickness rotator cuff tear, MRI is preferred to determine the size of the tear, the amount of muscle atrophy and tendon retraction, and the quality of remaining tissue for repair.

# INTRINSIC FACTORS CAUSING SHOULDER PAIN

## Periarticular Disorders

### Shoulder Impingement and Rotator Cuff Tendinopathy

One of the most common nontraumatic causes of shoulder pain is impingement with rotator cuff tendinopathy. In

1972, Neer[6] described his results of 100 anatomic shoulder dissections and coined the term *impingement syndrome*. Impingement may be defined as the encroachment of the acromion, coracoacromial ligament, coracoid process, or AC joint on the rotator cuff as it passes beneath them during glenohumeral motion. The function of the posterior rotator cuff is to abduct and externally rotate the humerus. The cuff with the biceps tendon serves as a humeral head depressor to maintain the head centered within the glenoid fossa as the cuff and to use the deltoid to elevate the arm.[56-58]

Controversy continues, however, as to the exact cause of impingement—that is, whether it is a primary, intrinsic, degenerative event within the tendon with superior migration of the head on arm elevation and secondary impingement on the acromion, or purely mechanical attrition of the tendon with primary impingement against the acromion. The mechanical impingement of the rotator cuff may be influenced by variations in the shape and slope of the acromion.[59,60] The supraspinatus outlet may become narrowed from proliferative spur formation of the acromion or degenerative changes in the AC joint. These changes, along with intrinsic degenerative changes of the rotator cuff, may lead to a rotator cuff tear, but the exact pathogenesis remains controversial. Many studies have found a strong correlation between degenerative hypertrophic spur formation, with its resulting narrowing of the supraspinatus outlet, and the presence of full-thickness cuff tears,[6,16,61-68] but clinical studies have failed to confirm whether hypertrophic changes in the coracoacromial arch are caused by the cuff lesions or whether these changes themselves cause the lesions.

Neer[6] developed a staging system for the description of impingement lesions of the shoulder. A stage I lesion involves edema and hemorrhage of the rotator cuff and typically is found in persons younger than 25 years who are active in athletics that involve repetitious overhead activities. The condition usually responds to conservative treatment that includes rest, anti-inflammatory medication, and physical therapy. Stage II lesions usually occur in persons in their 30s or 40s and represent the biologic response of fibrosis and thickening of the tendon after repeated episodes of mechanical impingement over time. Lesions are treated conservatively, as in stage I, but attacks may recur. If symptoms persist despite adequate conservative management for longer than 6 to 12 months, surgical intervention is warranted. Stage III lesions involve rotator cuff tears, biceps tendon rupture, and bone changes, and they rarely occur before age 40 years. Patients may present with pain, weakness, or supraspinatus atrophy, depending on the chronicity of the tear. Surgical treatment depends on the patient's age, loss of function, weakness, and pain.

Patients usually present to the clinician with a report of pain that has failed to resolve after a variable period. Pain can be sudden and incapacitating in cases of traumatic cuff tears, or more commonly it may manifest as a dull ache in cases of chronic impingement. Pain usually is located over the anterior and lateral aspects of the shoulder and may radiate into the lateral deltoid. It may worsen after sleeping on the affected extremity and is exacerbated by overhead activity. Tenderness on palpation may be elicited over the greater tuberosity and the long head of the biceps within the bicipital groove, indicating an associated biceps tendinitis. In cases with concomitant degenerative changes in the AC joint, tenderness may be noted on palpation over the AC joint, as an offending osteophyte impinges on the rotator cuff beneath.

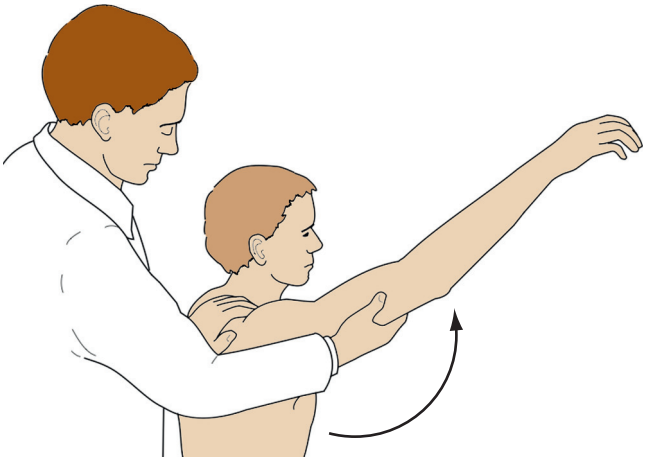

**Figure 46-13** The impingement sign is elicited by forced forward elevation of the arm. Pain results as the greater tuberosity impinges on the acromion. The examiner's hand prevents scapular rotation. This maneuver may be positive in other periarticular disorders. *(From Neer CS II: Impingement lesions.* Clin Orthop Relat Res *173:70, 1983.)*

The impingement sign as described by Neer[6] (Figure 46-13) is useful in the diagnosis of rotator cuff tendinopathy. The patient often describes a catch as the arm is brought into the overhead position. The patient may be observed to raise the arm by abduction and external rotation to clear the greater tuberosity of the acromion, bypassing the painful area. A typical painful arc usually occurs between 70 and 110 degrees of abduction. Neer[6] also described an impingement test that involves injection of lidocaine into the subacromial bursa. Relief of pain is a positive impingement test result and usually indicates rotator cuff origin of the shoulder pain.

Radiographs in the early stages of cuff tendinopathy may be normal or may reveal a hooked acromion. As the disease progresses, sclerosis, cyst formation, and sclerosis of the anterior third of the acromion and the greater tuberosity may be observed. An anterior acromial traction spur may appear on the undersurface of the acromion lateral to the AC joint and represents contracture of the coracoacromial ligament. Late radiographic findings include narrowing of the acromiohumeral gap, superior subluxation of the humeral head in relation to the glenoid, and erosive changes in the anterior acromion.[71] Arthrography, MRI, and ultrasound may be helpful in diagnosing a full-thickness tear of the rotator cuff in association with stage III disease. In some cases of chronic large rotator cuff tears, proximal migration of the humeral head leads to a pattern of degenerative arthritis termed *cuff-tear arthropathy*.

The choice of treatment and, frequently, its result are functions of the stage of the impingement and the response to pain. In stage I disease, in which little mechanical impingement occurs, most patients respond to rest. It is important to avoid immobilizing the shoulder for any period because contraction of the shoulder capsule and periarticular structures can produce an adhesive capsulitis. After a

period of rest, a progressive program of stretching and strengthening exercises generally restores the shoulder to normal function. Use of aspirin and other NSAIDs may shorten the symptomatic period. Modalities such as ultrasound, neuroprobe, and transcutaneous electrical nerve stimulation generally are not helpful. Patients with stage I or II disease may have a dramatic response to local injection of glucocorticosteroids and local anesthetic agents. For stage II disease in which fibrosis and thickening occur anteriorly, it is frequently better to perform the injection with a posterior approach. We prefer a combination of 3 mL of 1% lidocaine, 3 mL of 0.5% bupivacaine, and 20 mg of triamcinolone. This injection combines a short-acting anesthetic to help confirm the diagnosis, a longer-acting anesthetic for analgesic purposes, and a steroid preparation in a depot form.

An integrated program of occupational and physical therapy often precludes the need for surgery in patients with stage II disease. Job modification for persons with impingement syndrome caused by overuse may alleviate symptoms. Businesses are becoming increasingly aware of the cost savings associated with proper job ergonomics.[69,70]

The initial rehabilitation in stage II impingement consists of cessation of repetitive overhead activity. Use of ice, NSAIDs, and local injections also may be beneficial. Initial physical therapy includes passive, active-assisted, and active range of motion combined with stretching and mobilization exercises to prevent contracture. As pain and inflammation subside, isometric or isotonic exercises are used to strengthen the rotator cuff musculature. Isokinetic training at variable speeds and in variable positions is instituted before the patient is allowed to return to full activity. For patients with a job-related injury, it is crucial to review and modify job mechanics to prevent recurrent episodes that can cause further disability and may precipitate the need for surgery.[69]

Neer[16] suggested that a patient with refractory stage II disease may respond to division of the coracoacromial ligament and bursectomy of the subacromial bursa. Open anterior acromioplasty as described by Neer has become accepted as the procedure of choice for stage II and III impingement lesions, with many investigators reporting high success rates in treating impingement syndrome and rotator cuff tears.[71-74] Reported results show good and excellent relief of symptoms in 71% to 87% of patients treated with the open surgical procedure.[75-78]

In 1985, Ellman[50] described the technique of arthroscopic subacromial decompression. His initial results[51] and the results of others are comparable with those of open surgical techniques.[52,79] Arthroscopic subacromial decompression has become a widely accepted treatment for refractory stage II and III impingement lesions. The procedure can be performed as outpatient surgery, and because no deltoid is detached, as with the open technique, the procedure facilitates rehabilitation and increases overall recovery rates.

### Calcific Tendinitis

Calcific tendinitis is a painful condition around the rotator cuff that is associated with deposition of calcium salts, primarily hydroxyapatite.[80-82] The cause of calcific tendinitis is unknown. The commonly accepted cause is degeneration of the tendon, which leads to calcification through a dystrophic process.[82] A common clinicopathologic correlation is seen in three distinct phases of the disease process: the precalcific or formative phase, which can be relatively painless; the calcific phase, which tends to be quiescent and may last months to years; and the resorptive or postcalcific phase, which tends to be painful, as calcium crystals are resorbed.[80] Although calcific tendinitis is more common in the right shoulder, at least a 6% incidence of bilaterality has been reported. Patients with bilateral shoulder involvement often have the syndrome of calcific periarthritis, in which calcium hydroxyapatite crystals are found at multiple sites.[83] Patients usually present with impingement-type pain in the affected shoulder during overhead activity. The pain may seem to be out of proportion to any objective physical findings. The patient may describe difficulty sleeping on the shoulder and trouble falling asleep. Symptoms may last a few weeks or a few months.

The incidence of calcific tendinitis among asymptomatic persons varies from 2.7% to 20% in the literature. Most calcification occurs in the supraspinatus tendon, and 57% to 76.7% of patients are women. The average age of patients is 40 to 50 years.[80,84]

Codman[85] pointed out the localization of calcification within the tendon of the supraspinatus. He provided a detailed description of the symptoms and the natural history of this condition. In describing the phases of pain, spasm, limitation of motion, and atrophy, he noted the lack of correlation between symptoms and the size of the calcific deposit. According to Codman,[85] the natural history includes degeneration of the supraspinatus tendon, calcification, and eventual rupture into the subacromial bursa. During the latter phase, pain and decreased motion can lead to adhesive capsulitis (see Figure 46-8).

Several factors may affect localization of calcium within the supraspinatus. Many patients have an early stage of impingement that compresses the supraspinatus tendon on the anterior portion of the acromion.[6,16] This long-standing impingement may lead to local degeneration of tendon fibers. In patients without impingement, localization of calcium within the supraspinatus may be related to the blood supply of the rotator cuff, which normally is derived from an anastomotic network of vessels from the greater tuberosity or from the bellies of the short rotator muscles.[81] The watershed of these sources is just medial to the tendinous attachment of the supraspinatus.[86] Rathburn and Macnab[87] referred to this watershed as the critical zone and pointed out that during abduction this area was rendered ischemic.

Treatment of calcific tendinitis depends on the clinical presentation and the presence of associated impingement. Patients can have an acute inflammatory reaction that may resemble gout. The acute inflammation can be treated with a local glucocorticoid injection, NSAIDs, or both. Ultrasound may be beneficial. If impingement is associated, treatment depends on the stage at presentation. The radiographic appearance of the calcification can direct and perhaps predict the response to therapy. In the resorptive state, deposits appear floccular, suggesting that the process is in the phase of repair and that a conservative program is indicated.

Patients with discrete calcification and perhaps associated adhesive capsulitis (see Figure 46-8) may be at a stable

phase, in which calcium produces a mechanical block and is unlikely to be resorbed. For these patients, mechanical removal of calcific deposits and correction of associated pathologic lesions may be necessary.[88-90] Percutaneous disruption of calcified areas may be performed using a needle directed by fluoroscopy. This technique allows lavage and injection, but it does not treat associated impingement. Subacromial arthroscopy allows mechanical débridement of calcific deposits under direct visualization. This technique can be combined with arthroscopic removal of the inflamed bursa and decompression of associated impingement. Improved results have been noted with complete removal of calcific deposits.[91] In many cases of refractory calcific tendinitis associated with impingement, open or arthroscopic acromioplasty, subacromial bursectomy, and decompression are indicated.

### Rotator Cuff Tear

**Pathophysiology.** Spontaneous tear of the rotator cuff in an otherwise healthy person is rare.[16] It can occur in patients with RA or systemic lupus erythematosus as part of the pathologic process with invasion from underlying pannus. Metabolic conditions such as renal osteodystrophy and agents such as glucocorticoids occasionally are associated with cuff tears. Most patients report a traumatic episode, such as falling on an outstretched arm or lifting a heavy object. The usual presenting symptoms are pain and weakness of abduction and external rotation. Crepitus and even a palpable defect may be associated with the tear. Long-standing tears generally are associated with atrophy of the supraspinatus and infraspinatus muscles. It may be difficult to differentiate painful tendinitis from a partial-thickness or a small full-thickness cuff tear.

The exact cause of cuff tendinopathy continues to be controversial.[86,90,92,93] Most likely, the pathophysiology involves a combination of factors, including decreased vascularity and cellularity of the tendon, along with changes in the collagen fibers of the tendon that occur with aging.

Loss of motion with subsequent capsular tightness, particularly in the posterior capsule, may lead to cephalad migration of the humeral head, with subsequent impingement of the cuff under the coracoacromial arch.[94] Rehabilitation exercises focus on regaining a normal range of motion. To achieve full, painless motion, the normal relationship of glenohumeral to scapulothoracic motion must be achieved.[13,14,95]

**Diagnosis—History.** Patients with nontraumatic tears of the rotator cuff report symptoms of chronic impingement. Loss of motion and a feeling of stiffness are often noted with extremes of motion, along with difficulty during activities of daily living, such as combing one's hair, hooking a bra strap, putting on a shirt or coat, and reaching into the back pocket. In chronic cases of cuff tendinopathy, loss of motion usually occurs. Limitation of internal rotation caused by posterior capsular contracture occurs initially and is often associated with posterior shoulder pain with adduction of the ipsilateral shoulder. Further shoulder impingement occurs with forward flexion because of superior migration of the humeral head against the anterior inferior acromion. This upward translation is analogous to the action of a yo-yo climbing on a string.[94,96] Over time, loss of forward flexion, abduction, and external rotation occurs with passive and active motion of the shoulder.

**Diagnosis—Imaging.** In acute cases, a history of trauma, such as a fall onto the affected shoulder, may be reported. In cases involving an anterior shoulder dislocation with subsequent profound weakness of the rotator cuff, a large cuff tear or a greater tuberosity avulsion should be suspected, in addition to axillary nerve palsy. In younger patients, traumatic failure of the cuff under tensile overload may result in cuff failure caused by forced adduction of the affected shoulder or active abduction against resistance, and this outcome may occur with traumatic dislocation. Repetitive tensile overload also can result in partial rotator cuff tears in an athlete whose sport entails repetitive overhead actions.

Plain radiographs are used in the initial evaluation of impingement-type shoulder pain with cuff tendinopathy. An impingement series should be ordered, including an anteroposterior radiograph with a 30-degree cephalic tilt (the Rockwood view), which can reveal osteophytes of the anterior os acromion and AC joint; a scapular Y view with a 10-degree cephalic tilt (the supraspinatus outlet view), which can evaluate the type of acromion and reveal anterior and AC osteophytes; and an axillary view, which can evaluate the acromion for possible os acromiale. Calcific deposits within the rotator cuff tendon can be viewed best with rotational anteroposterior radiographs. Cuff arthropathy should be suspected if the acromial-humeral distance is less than 7 mm, or with the presence of cyst formation within the greater tuberosity, humeral head osteopenia, sclerosis around the greater tuberosity, or humeral head collapse. In advanced stages of cuff arthropathy, complete loss of glenohumeral joint space may be seen with superior migration and abutment of the humeral head against the undersurface of the acromion.[56]

In the past, shoulder arthrography was considered the "gold standard" for diagnosing full-thickness and partial-thickness rotator cuff tears, with greater than 90% sensitivity and specificity.[30,97] Currently, arthrography with CT or MRI is routinely used to diagnose rotator cuff disease, including full-thickness and partial-thickness tears.

Ultrasonography has been accurate in the diagnosis of full-thickness rotator cuff tears.[36,98-101] Ultrasonography offers the advantages of being inexpensive and noninvasive, but disadvantages include unproven effectiveness in determining subacromial impingement, capsular and labral abnormalities, and partial cuff tears. The procedure and its results are technician dependent. Ultrasonography may have a useful role in determining the post-operative integrity of the cuff repair.[35]

MRI has been invaluable in evaluating rotator cuff tears. The sensitivity and specificity of MRI for diagnosing full-thickness cuff tears are 100% and 95%.[102] With the use of gadolinium or saline solution, partial tears that are otherwise difficult to detect with conventional imaging can be detected.

Diagnosing cuff tears with MRI usually is based on discontinuity of the tendon on T1-weighted images and consistency with fluid signal on T2-weighted images. Ancillary findings include fluid in the subacromial space on T2-weighted images, loss of the subacromial fat plane on T1-weighted images, and proliferative spur formation of

the acromion or AC joint. Large, chronic cuff tears also may be associated with cephalad migration of the humeral head and fatty atrophy of the supraspinatus muscle. Periarticular soft tissues, including the capsulolabral complex and the biceps tendon, as well as the rotator cuff, can be thoroughly examined. The degree of tear and tendon retraction and evidence of muscle atrophy can be evaluated, all of which are crucial in pre-operative planning for possible cuff repair.

**Treatment—Nonsurgical.** Codman and Akerson[61] recommended early operative repair for acute full-thickness rotator cuff tears and reported the first documented repair in 1911. McLaughlin[63] recommended early repair in cases of grossly displaced tuberosity fractures or massive tears. Several other clinical studies have supported the concept that a full-thickness tear does not preclude good shoulder function. DePalma[103] reported that 90% of patients with rotator cuff tears responded to conservative measures, such as rest, analgesics, anti-inflammatory agents, and physiotherapy.

The reported percentage of patients responding to nonsurgical treatment in the literature varies from 33% to 90%.[4,15,104] Conservative treatment includes pain control with NSAIDs, ultrasound, application of heat before shoulder stretching and exercise, and application of ice after overhead activity. Deep massage therapy is used to reduce trigger point tenderness within the trapezius, levator scapulae, and periscapular muscles. Patients taking anti-inflammatory medications on a long-term basis are monitored periodically for evidence of gastrointestinal bleeding and for hepatic or renal toxicity. Opiate-based drugs are used only in the acute setting, such as after a fall, or in the perioperative period.

Steroid and local anesthetic injections are used when the patient has significant pain that prohibits rehabilitation. Injections may be repeated once every 3 months if needed; injection into the cuff tendon is to be avoided. If the patient fails to improve after 3 months of conservative treatment or does not continue to improve after three sequential injections, surgical options should be discussed.

The mainstay of conservative therapy is exercise. Rehabilitation stresses pain relief with exercises aimed at restoring shoulder motion and strengthening remaining cuff muscles, deltoid muscles, and scapular stabilizers. Therapy can be divided into three phases. The goals of the initial phase of therapy are to relieve pain and restore shoulder motion. Motion therapy includes pendulum exercises, passive motion with use of a wand with assistance of the uninvolved shoulder, an overhead pulley system, and posterior capsular stretching. The arc of motion is gradually increased and is guided by the patient's discomfort to avoid painful impingement arcs.

The second phase of therapy is entered after the patient has return of motion and little discomfort with overhead activity. Emphasis is placed on strengthening the remaining rotator cuff musculature and deltoid and periscapular muscles. Strengthening with elastic surgical tubing provides variable degrees of resistance, depending on the size of the tubing. Initial strengthening is performed out of the impingement arc (with 70 to 120 degrees of shoulder flexion). The goal of this phase is to strengthen the shoulder to prevent dynamic proximal humeral migration with impingement during active shoulder elevation.[56,59] Normal shoulder kinematics rely on combined and synchronous glenohumeral flexion and scapular rotation.[57,90] In addition to strengthening the cuff and deltoid, the scapular rotators, including the trapezius and the serratus anterior muscles, are emphasized.[105]

After the patient has successfully completed phase two of the rehabilitation program with minimal symptoms and good shoulder function, the final phase is entered. Phase three is characterized by a gradual return to normal overhead activities, including work and sporting activities. This part of the rehabilitation program should be tailored to the individual patient's needs and the demands placed on the shoulder.

**Treatment—Surgical.** A Cochrane review of the effectiveness of surgery for rotator cuff disease failed to reach any firm conclusions about the effectiveness or safety of rotator cuff surgery.[106]

Severity and duration of pain are the primary indications for surgical intervention in a rotator cuff tear. Other factors important in surgical decision making include shoulder dominance, activity level, physiologic age, acuteness of the tear, degree of the tear, loss of function, the amount of tendon retraction, and fatty atrophy of the remaining cuff musculature.

A systematic review of indications for rotator cuff surgery found that earlier surgical intervention may be needed for patients with cuff tears who have weakness and significant functional disability. In addition, older chronologic age did not portend a worse outcome; however, pending workman's compensation claims negatively affected treatment results.[107]

**Acute Tears.** Acute tears of the rotator cuff can be treated with conservative measures of periscapular and cuff strengthening along with capsular stretching to restore motion. Early surgical intervention should be considered in a young patient, especially an athlete whose sport entails repetitive overhead actions. Conservative shoulder rehabilitation should be maintained for 3 to 6 months before a decision is made regarding surgery for an older sedentary patient, in whom functional results without surgery may be acceptable. Many older patients may function well with chronic cuff tears, but they may become debilitated if an acute tear is superimposed on chronic changes. Surgical intervention may be required in these cases to return the patient to baseline function by repairing the acute tear and attempting to repair the chronic tear if possible.

**Chronic Tears.** For elderly patients whose pain and weakness do not create a functional problem, a conservative program is preferable for chronic tears. Pain that is unresponsive to conservative management is the main indication for surgery in an older patient with a chronic rotator cuff tear. In these cases, surgery should be considered on an individual basis after at least 3 months of conservative treatment, including subacromial steroid injection. If the cuff tear is massive and irreparable, débridement and subacromial decompression may provide good pain relief without extensive surgery and prolonged immobilization.[51,79,108-112] In a younger patient with a chronic tear and weakness, surgery to repair the cuff may be indicated to improve strength and prevent further extension of the tear.[110] In cases of rotator cuff arthropathy with glenohumeral joint degeneration, a reverse total shoulder replacement may be indicated. This

**Figure 46-14** Reverse total shoulder replacement in a 72-year-old man who had severe cuff arthropathy.

type of total shoulder replacement reverses the normal relationship between scapular and humeral components, moving the center of rotation medially and distally to increase the lever arm length of the deltoid muscle. The deltoid compensates for the deficient rotator cuff, allowing as near-normal function as possible (Figure 46-14). A recent publication also suggested reverse total shoulder arthroplasty for the treatment of irreparable rotator cuff tear with disability and no glenohumeral arthritis.[113]

**Economic Aspect of Rotator Cuff Repair.** With the recent shift of health care management toward reducing costs and efficient treatment, rotator cuff repairs have become an area of consideration. Evaluation fees, including visit and imaging fees, have gradually increased in recent years, generating a larger burden on both the health care system and the economy at large. A common aspect of health care costs that is not taken into consideration is the opportunity cost faced by patients when they choose to seek and follow medical advice. To fully understand the scope of the financial impact of rotator cuff repair, indirect costs such as travel costs to and from medical facilities, missed wages, decrease in labor and productivity, and disability support must be added into the equation. Indirect costs, combined with the increased costs reflected in Table 46-2, can show the real fiscal significance.

In subsequent debates it has been argued whether operative treatment is superior to nonoperative treatment, with both sides utilizing hidden costs as the deciding factor. Mather et al.[114] published a study showcasing this exact quandary of operative versus nonoperative treatment in cost reduction and societal benefit. The investigators utilized a decision-based, semirandom optimization framework, the Markov decision process, in comparing the repair of full-thickness tears to nonoperative management after an assumed failure of a course of nonoperative therapy. Patients in the model were reimbursed by the standards of average Medicare payouts at the time and several indirect costs, such as those previously mentioned, were used as measuring points. The results showed a significant cost efficacy at any age with repair, with a substantial impact on patients younger than 40 years because of their increased earning potential and financial activity.[114] Although the savings margin was increased for all ages, it was much more reduced in persons older than 70 years. The total savings calculated was approximately $3.44 billion, and the authors commented that although surgery is not indicated for all cases, it assisted with the global costs of rotator cuff tear management.

A more recent level I study conducted in Norway included 103 patients randomized into nonoperative or operative management for both full- and partial-thickness tears not exceeding 3 cm.[115] Although this study did not focus on the economic aspect of care, the results favored operative management and by doing so indicated certain financial benefits. The two major areas in which operative treatment was shown to excel and have a meaningful influence were in quality of life as measured by several outcome measures and rate of retearing and persistent tears during a 5-year period. The assumption can be made that with increased quality of life and decreased symptomatic retearing, patients most likely stayed on disability for shorter periods and fewer resources were allocated to symptom assessment and treatment.

Although these studies highlight certain aspects of the economics of rotator cuff repair, several limitations must be considered, such as sample size, assumptions made to develop the logic model, and financial motivation. At present there is still a dearth of analysis with regard to the fiscal environment surrounding health care costs for persons undergoing management of symptomatic rotator cuff tears.

## Bicipital Tendinitis and Rupture

The long head of the biceps passes through the bicipital groove, crosses over the head of the humeral, and inserts on the superior rim of the glenoid (see Figure 46-1A).[116] The biceps tendon aids in flexion of the forearm, supination of the pronated forearm if the elbow is flexed, and forward elevation of the shoulder.[4] Bicipital tendinitis, subluxation or dislocation of the biceps tendon within the bicipital groove, and rupture of the long head of the biceps generally are associated with anterior shoulder pain.

Bicipital tendinitis is sometimes an associated feature of a rotator cuff tear. The rotator cuff tear compromises centering of the humeral head on the glenoid. This compromise results in increased mechanical loading of the long head of the biceps, which initiates a hypertrophic tendinitis.[117]

Dislocation of the long head of the biceps usually is combined with a lesion of the subscapularis tendon.[9] Isolated rupture of the long head of the biceps tendon is rare when the rotator cuff is intact. Rupture of the long head of the biceps is common, however, when a co-existing rotator cuff tear is present.[118] The effects of rotator cuff tear and concomitant biceps tendon rupture on strength can be substantial.[9]

Early phases of bicipital tendinitis are associated with hypervascularity, edema of the tendon, and tenosynovitis.[119]

Persistence of this process leads to adhesions between the tendon and its sheath, along with impairment of the normal gliding mechanism in the groove. Stretching of the adhesions may be associated with chronic bicipital tendinitis.[120] The diagnosis of bicipital tendinitis is based on localization of tenderness. It is often confused with impingement symptoms and is frequently seen with an impingement syndrome.[21] Isolated bicipital tendinitis can be differentiated by the fact that the tender area migrates with the bicipital groove as the arm is abducted and externally rotated. Many eponyms are associated with tests to identify bicipital tendinitis.[4] Yergason's supination sign refers to pain in the bicipital groove when the examiner resists supination of the pronated forearm with the elbow at 90 degrees. Ludington's sign refers to pain in the bicipital groove when the patient interlocks the fingers on top of the head and actively abducts the arms.

Biceps tendon rupture can occur in some patients who report no history of shoulder pain. Patients often report an acute onset of pain and ecchymosis around the anterior shoulder and sagging of the biceps muscle belly. In these cases, a concomitant rotator cuff injury should be excluded by clinical examination. More often, the biceps tendon rupture is preceded by painful shoulder symptoms that often improve or disappear after the rupture.[120,121]

Treatment generally is conservative and consists of rest, analgesics, NSAIDs, and local injection of glucocorticoids. The use of ultrasound and a neuroprobe is more beneficial in this condition than in isolated rotator cuff tendinitis. Patients with refractory bicipital tendinitis and recurrent symptoms of subluxation are treated by arthroscopic biceps tenodesis or open tenodesis—that is, opening the bicipital groove and resecting the proximal portion of the tendon with tenodesis of the distal portion into the groove or beneath the pectoralis tendon.

## Acromioclavicular Disorders

The AC joint is a common source of shoulder pain. Acute causes of AC joint pain are often related to direct trauma of the affected shoulder that may result in a distal clavicle injury with an intra-articular chondral fracture, or in AC joint instability from ligamentous disruption.[122]

Post-traumatic distal clavicle osteolysis, with resorption of the distal clavicle, may ensue 4 weeks after a shoulder injury, leading to AC joint pain.[123,124] Osteolysis may be caused by microfracture of the subchondral bone and subsequent attempts at repair.[125] Other authors believe the cause to be an autonomic nerve dysfunction affecting the blood supply to the clavicle. The increased blood supply leads to resorption of bone from the distal clavicle.[123,126] More commonly, chronic osteolysis results from repetitive microtrauma to the AC joint from activities such as weight lifting, gymnastics, and swimming.[125,127,128]

The underlying pathophysiology is believed to be an inflammatory process caused by stress fracture of the subchondral bone with hyperemic resorption of the distal clavicle.[125,129] Other causes of osteolysis include rheumatoid arthrosis, hyperparathyroidism, and sarcoidosis, which should be considered in the differential diagnosis, especially in bilateral cases.[123,124] Patients with atraumatic osteolysis of the distal clavicle should be forewarned that bilateral involvement may occur; an incidence of 70% was reported for one study with long-term follow-up.[130] Other chronic causes of AC pain include idiopathic, intra-articular disk disease, post-traumatic degenerative arthrosis from joint incongruity, primary degenerative arthrosis, and rheumatoid arthrosis.

Evaluation should always include a detailed history, physical examination, and radiographic evaluation. A history of trauma to the AC joint from a direct fall or blow to the ipsilateral shoulder may be reported. Less commonly, the AC joint may have been injured indirectly, as during a fall on the outstretched arm with forces transmitted through the arm to the AC joint.[122,131] Patients with osteolysis of the distal clavicle sometimes report a history of acute trauma, although the more common cause is repetitive microtrauma to the AC joint caused by activities such as weight lifting or gymnastics.[123,124,127,128]

Patients frequently report having pain over the AC joint when adducting the ipsilateral shoulder, such as during a golf swing or when buckling a seat belt. Often, pain occurs when the patient sleeps on the affected shoulder. Athletes may experience AC joint pain when bench pressing and when performing push-ups and dips.[130,132,133] Pain and weakness of the affected shoulder also may be experienced with forward flexion and adduction of the arm.[123]

On physical examination, a visible step-off may be observed between the medial acromion and the distal clavicle, indicating a probable AC separation. Pain usually can be elicited on direct palpation of the AC joint and is made worse by a cross-arm adduction maneuver. This test is performed by internally rotating the arm, which is maximally adducted across the chest, and is considered positive if pain is produced in the AC joint (see Figure 46-3D). Pain also may be elicited by moving the arm from a horizontally abducted position to the extended position and upon maximal internal rotation of the shoulder.[132,134] These tests cause rotation and compression of the AC joint and are sensitive but less specific. They also may be positive with other disorders of the shoulder, such as posterior capsular stiffness.[135]

Frequently, AC joint pain co-exists with subacromial impingement and rotator cuff disease. In these cases, impingement signs are positive, and rotator cuff weakness may be present. Otherwise, no muscle weakness should be detectable on manual resistance testing, and no evidence of muscle atrophy should be found.[130,135,136] The AC joint and the subacromial space may require injection on separate occasions to determine the true source of the symptoms. Some physicians have noticed an association of AC joint symptoms with shoulder instability.[130] Glenohumeral motion can vary, depending on chronicity and isolation of the problem to the AC joint. In isolated cases, some loss of internal rotation of the affected shoulder may be caused by pain.

Radiographs should include anteroposterior views of the shoulder in the scapular plane in neutral, internal, and external rotation; a transcapular Y view; an axillary view; and a 15-degree cephalic tilt view of the AC joint at 50% penetrance, as described by Zanca (see Figure 46-4).[20] Stress views may be obtained by strapping 5- to 10-lb weights to the forearms and determining AC separation. Comparing the coracoclavicular distance of both shoulders also may be

helpful. When clinically indicated, cervical spine radiographs should be obtained to exclude cervical spondylosis.

Radiographic evaluation may reveal AC joint arthrosis with microcystic changes in the subchondral bone, sclerosis, osteophytic lipping, and joint space narrowing.[137] In cases of osteolysis, radiographs may reveal loss of subchondral bone detail with microcystic appearances in the subchondral region of the distal clavicle and osteopenia of the lateral one-third of the clavicle.[124,125,127,128] In late stages of osteolysis, resorption of the distal end of the clavicle results in marked widening of the AC joint and sometimes complete resorption of the distal clavicle. AC separation may be evident with widening of the coracoclavicular distance and post-traumatic ossification of the coracoclavicular ligaments.

AC symptoms do not always correlate with the radiographic appearance of the joint. DePalma[138] found AC joint degeneration to be an age-related process, with symptoms not always correlating with radiographic findings of AC joint arthrosis.[20] AC joint pain may occur despite normal findings of radiographs.[139]

A Tc 99m phosphate bone scan may assist in the diagnosis, revealing increased uptake in the distal clavicle and the medial acromion.[125] In cases of atraumatic osteolysis of the distal clavicle, increased uptake may be isolated to the distal clavicle, but in approximately 50% of cases, scintigraphic activity of the adjacent medial acromion is increased.[130] The bone scan may reveal pathologic changes in the AC joint when plain radiographs appear normal.

In selected cases, MRI can be valuable in determining a diagnosis and evaluating the glenohumeral and subacromial regions for co-existing disease (Figure 46-15). AC joint involvement may reveal increased fluid with synovitis, soft tissue enlargement, and periarticular ossifications with encroachment on underlying bursal and cuff tissue.

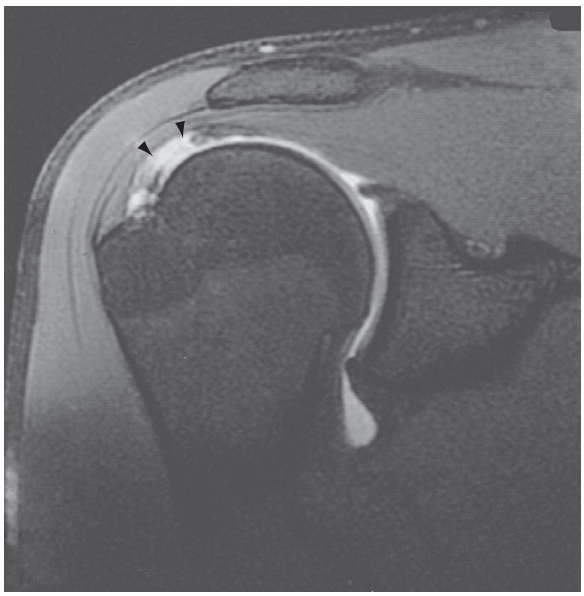

**Figure 46-15** Sagittal section MRI of the shoulder in a 32-year-old weight lifter with shoulder pain. A fat-suppressed proton density fast spin-echo image shows a bursal-side high-grade partial cuff tear *(arrowheads)*.

Patients with AC joint pain usually respond well to nonoperative treatment; however, complete relief of symptoms may require an extended period. Conservative therapy includes application of heat, use of NSAIDs, steroid injections, shoulder rehabilitation, and avoidance of painful positions and activities. Steroid injections are repeated at 3-month intervals if painful conditions persist.

Open resection of the distal clavicle for chronic AC joint pain was initially reported by Gurd[140] and by Mumford,[141] both with good results. Since that time, other surgeons have reported similar good results with open resection; however, significant morbidity, such as disruption of the deltotrapezial fascia and anterior deltoid rupture, can occur.[124,124,137,139,142] Arthroscopic resection of the distal clavicle has been described with results similar to those of open resection.[10,129,134,136,143-146]

## Glenohumeral Disorders

The various arthritides that affect the shoulder joint are discussed in detail in other chapters. They are presented here to address aspects that are unique to the glenohumeral joint. The usual presentation of intra-articular disorders consists of pain with motion and symptoms of internal derangement, such as locking and clicking. Pain is generalized throughout the shoulder girdle and sometimes is referred to the neck, back, and upper arm. The usual response to pain includes decreased glenohumeral motion and substitution with increased scapulothoracic mobility. Patients with adequate elbow and scapulothoracic motion require little glenohumeral motion for activities of daily living, and patients with glenohumeral arthrodesis can achieve adequate function.[147,148] The response to pain consists of diminution of motion and secondary soft tissue contractures with muscle atrophy. With increasing weakness and involvement of adjacent joints, pain, limitation of motion, and weakness can cause a substantial functional deficit.

## Inflammatory Arthritis

Although the most common inflammatory arthritis involving the shoulder joint is RA, other systemic disorders such as systemic lupus erythematosus, psoriatic arthritis, ankylosing spondylitis, reactive arthritis, and scleroderma may cause glenohumeral degeneration. Motion is limited by splinting of the joint with secondary soft tissue contractures or by primary soft tissue involvement with scarring or rupture. Plain radiographs confirm glenohumeral involvement (Figure 46-16A). Narrowing of the glenohumeral joint space may occur, with erosion and cyst formation and without significant sclerosis or osteophytes. As the disease progresses, superior and posterior erosion of the glenoid with proximal subluxation of the humeral head may occur. Eventually, secondary degenerative changes and even osteonecrosis of the humeral head may occur.

Treatment is initially conservative and is directed toward controlling pain, inducing a systemic remission, and maintaining joint motion through physical therapy. The use of intra-articular glucocorticoids may be beneficial in controlling local synovitis. In RA, the involvement of periarticular structures with subacromial bursitis and rupture of the rotator cuff magnifies the functional deficit. When synovial

Notice the preservation of the subacromial space, suggesting an intact rotator cuff.

cartilage interactions produce significant symptoms and radiographic changes that cannot be controlled by conventional therapy, glenohumeral resurfacing should be considered.

When following up on a patient with RA who has shoulder involvement, the rheumatologist should assess range of motion carefully and obtain radiographs periodically. Patients with progressive loss of motion or radiographic destruction should be referred for evaluation for possible surgical treatment. The treatment of choice is an unconstrained total shoulder arthroplasty.[149,150] Total shoulder arthroplasty is best performed in patients with RA before end-stage bony erosion and soft tissue contractions have occurred.[151,152] Acute inflammatory arthritis of the glenohumeral joint may be associated with gout, pseudogout, hydroxyapatite deposition of renal osteodystrophy, and recurrent hemophilic hemarthrosis.

## Osteoarthritis

Osteoarthritis of the glenohumeral joint is less common than that in the hip, its counterpart in the lower extremity; this condition is caused by non–weight-bearing characteristics of the shoulder joint and the distribution of forces throughout the shoulder girdle. Osteoarthritis is divided into conditions associated with high unit loading of articular cartilage and conditions in which an intrinsic abnormality within the cartilage causes abnormal wear at normal loads. Because the shoulder is normally a non–weight-bearing joint and is not usually susceptible to repeated high loading, the presence of osteoarthritis of the glenohumeral joint should alert the physician to consider other factors. Has the patient engaged in unusual activities, such as boxing, heavy construction, or long-term use of a pneumatic hammer? Has some disorder, such as epiphyseal dysplasia, created joint incongruity with high unit loading of the articular cartilage? Is this a neuropathic process caused by diabetes, syringomyelia, or leprosy? Have associated hemochromatosis, hemophilia, or gout altered the ability of articular cartilage to withstand normal loading? Is unrecognized chronic dislocation responsible?

Pain is the usual presentation, but generally it is not as acute or it may be associated with the spasm seen in inflammatory conditions. Plain radiographs show narrowing of the glenohumeral joint, osteophyte formation, sclerosis, and some cyst formation (Figure 46-16B). Because the rotator cuff usually is intact, less bone erosion of the glenoid and proximal subluxation of the humerus is noted. Patients with osteoarthritis of the glenohumeral joint frequently do well with functional adjustments and conservative therapy. Analgesics and NSAIDs may provide symptomatic relief. The use of glucocorticoid injections is less beneficial, unless evidence of synovitis is observed. Patients with severe involvement who fail to respond to conservative therapy are best treated with shoulder arthroplasty.

## Osteonecrosis

Osteonecrosis of the shoulder refers to necrosis of the humeral head seen in association with a variety of conditions. Symptoms are due to synovitis and joint incongruity resulting from resorption, repair, and remodeling.

The most common cause of osteonecrosis of the shoulder is avascularity resulting from a fracture through the anatomic neck of the humerus.[153] Fracture through this area disrupts intramedullary and capsular blood supplies to the humeral head.[154] Another common cause of osteonecrosis of the shoulder is steroid therapy provided in conjunction with organ transplantation, systemic lupus erythematosus, or asthma. Other conditions associated with osteonecrosis of the humeral head include hemoglobinopathies, pancreatitis, and hyperbarism.

Early diagnosis is difficult because the presence of symptoms is often delayed. Bone scans may be helpful in early cases, before radiographic changes are evident. MRI is highly sensitive and is more specific than scintigraphy. Plain radiographs show progressive phases of necrosis and repair. In early stages, the films may be normal or may show osteopenia or bone sclerosis. A crescent sign representing subchondral fracture or demarcation of the necrotic segment appears during the reparative process. Patients who fail to undergo remodeling show collapse of the humeral head with

secondary degenerative changes. A considerable discrepancy is often noted between symptoms and radiographic involvement. Patients with extensive bone changes may be asymptomatic. Treatment should be directed by the patient's symptoms rather than by the radiographs and is similar to that provided for osteoarthritis. Arthroscopy occasionally is helpful by removing loose chondral fragments and débriding chondral incongruities.[155] Patients with severe symptoms that cannot be controlled by conservative means are best treated with unconstrained shoulder arthroplasty, hemiarthroplasty, or resurfacing arthroplasty.[149]

## Cuff-Tear Arthropathy

In 1873, Adams described the pathologic changes that characterize RA of the shoulder and a condition that since that time has been referred to as "Milwaukee shoulder" or cuff-tear arthropathy.[156] McCarty called the condition Milwaukee shoulder and reported that factors predisposing to this syndrome included deposition of calcium pyrophosphate dihydrate crystals, direct trauma, chronic joint overuse, chronic renal failure, and denervation.[157,159] Patients with Milwaukee shoulder have elevated levels of synovial fluid 5-nucleotidase activity and elevated levels of synovial fluid inorganic pyrophosphate and nucleotide pyrophosphohydrolase activity.[158]

Neer and colleagues[159] reported a similar condition in which untreated massive tears of the rotator cuff with proximal migration of the humeral head are associated with erosion of the humeral head. Erosion of the humeral head differs from that seen in other arthritides and is presumed to be caused by a combination of mechanical and nutritional factors acting on the superior glenohumeral cartilage.

Patients with cuff-tear arthropathy present a difficult therapeutic problem because bone erosion and disruption of the cuff jeopardize the functional result from an unconstrained prosthesis.[151] Hemiarthroplasty or a reverse total shoulder arthroplasty may be indicated.[160,161] The major challenge in treating cuff-tear arthropathy is to determine which patients with massive rotator cuff tears will proceed to the syndrome of cuff-tear arthropathy. Patients with massive rotator cuff tears in whom localized calcium pyrophosphate disease develops may be predisposed to further proximal migration and further joint destruction. This situation poses a dilemma for the treating physician. Many patients with massive rotator cuff tears remain stable and require little or no treatment. Occasionally, symptomatic patients can be treated by arthroscopic débridement of the cuff tear. In a recent study, patients who had massive rotator cuff tears without arthritis did well when treated with reverse total shoulder arthroplasty.[113] It is crucial to define the patient who will proceed to the syndrome of cuff-tear arthropathy. If crystal deposition disease predisposes patients to proximal migration and joint destruction, joint aspiration with crystal analysis and scintigraphy to determine synovial reaction may be helpful diagnostic tools.

Hamada and co-workers[162] followed up 22 patients with massive rotator cuff tears who were treated conservatively. Radiographic findings included narrowing of the acromiohumeral interval and degenerative changes in the humeral head, tuberosities, acromion, AC joint, and glenohumeral joint. Five of seven patients followed up for longer than 8 years progressed to cuff-tear arthropathy. Investigators concluded that progressive radiographic changes were associated with repetitive use of the arm in elevation, rupture of the long head of the biceps, impingement of the humeral head against the acromion, and weakness of external rotation.[162]

## Septic Arthritis

Septic arthritis can masquerade as any of the conditions classified as periarticular or glenohumeral disorders. Sepsis must be included in any differential diagnosis of shoulder pain because early recognition and prompt treatment are necessary to achieve a good functional result. The diagnosis is confirmed by joint aspiration with synovial fluid analysis and culture. Cultures should include aerobic, anaerobic, mycobacterial, and fungal studies.

## Labral Tears

The glenoid labrum increases the depth of the glenoid and serves as an anchor for the attachment of the glenohumeral ligaments. Historically, labral tears have been difficult to diagnose. Findings on physical examination can be confused with impingement and rotator cuff tendinopathy and bicipital tendinitis. Diagnosis can be confirmed with MRI-arthrography, CT-arthrography, and DCAT.[24] Arthroscopy has greatly increased our knowledge of the glenoid labrum in normal and pathologic situations and has aided clinicians in the diagnosis and treatment of labral lesions.

Labral tears can be divided into tears associated with symptoms of internal derangement and tears associated with anterior or posterior instability. A soft tissue Bankart lesion is associated with a tear of the anterior band of the inferior glenohumeral ligament and with anterior instability. Isolated labral tears that do not involve detachment of the ligaments can cause internal derangement and may have an arthroscopic appearance similar to that of a meniscal tear of the knee.

Andrews and associates[2] first described lesions of the anterior superior labrum in athletes whose sport entails throwing; these lesions were often associated with biceps tendon tears (10%), which may result from traction of the biceps tendon. Snyder and co-workers[163] introduced the term *SLAP lesion* in 1990 to describe an injury involving the long head of the biceps tendon and the superior portion of the glenoid labrum.

The long head of the biceps tendon originates at the supraglenoid tubercle and the glenoid labrum in the superior-most portion of the glenoid. The major portion of the tendon blends with the posterior superior aspect of the labrum. The most common mechanism of a SLAP injury is a fall onto an outstretched arm with the shoulder in abduction and slight forward flexion.[163] The lesion also can result from acute traction on the arm and from an abduction and external rotation mechanism.[164,165]

Patients usually report pain with overhead activities and a frequent catching or popping sensation in the shoulder. The most reliable diagnostic test is O'Brien's test. The test is performed against resistance with the arm in forward flexion and with the elbow extended and the forearm pronated. In the second part of the test, the arm is supinated.

Less pain during the latter part of the test suggests a SLAP lesion.[163] The most accurate diagnostic test is MRI-arthrography with gadolinium.[166] Treatment for symptomatic SLAP lesions is surgical.

## Adhesive Capsulitis

Adhesive capsulitis, or frozen shoulder syndrome (FSS), is a condition characterized by limited motion of the shoulder joint with pain at the extremes of motion. It was first described by Putman[167] in 1882 and later by Codman.[85] The initial presentation is pain, which is generalized and is referred to the upper arm, back, and neck. As pain increases, loss of joint motion ensues. The process generally is self-limiting and in most cases resolves spontaneously within 10 months, unless an underlying problem is present.

The exact cause of FSS is unknown.[90,168] It is frequently associated with conditions such as diabetes mellitus, parkinsonism, thyroid disorders, and cardiovascular disease. When one of these conditions exists, a history of some mild trauma that initiated the frozen shoulder is often reported. Major skeletal trauma and soft tissue injury may co-exist with FSS. It also may be seen with a variety of other conditions, including apical lung tumor, pulmonary tuberculosis, and cervical radiculopathy, as well as after myocardial infarction.[169-171] In one review of FSS, 3 of 140 patients with this syndrome had local primary invasive neoplasms.[172] Another study described three patients with adhesive capsulitis who subsequently were found to have a neoplastic lesion of the midshaft of the humerus.[173] In a high-risk patient with an underlying disorder, even minor surgery or trauma in a remote location, such as the hand, can precipitate FSS.

The pathophysiology involves a diffuse inflammatory synovitis with subsequent adherence of the capsule and loss of the normal axillary pouch and joint volume, which leads to significant loss of motion. Capsular contracture is thought to result from adhesion of the capsular surfaces or fibroblastic proliferation in response to cytokine production.[168,174,175] The condition is common in women in their 40s and 50s. Typically, the patient relays a history of diffuse, dull aching around the shoulder, with weakness and loss of motion occurring over a few months.

Usually, three distinct clinical stages of the syndrome can be identified. Stage one is the painful inflammatory or freezing phase. During this stage, pain is severe, is exacerbated by any attempts at movement, and usually lasts a few weeks or months. The patient usually feels most comfortable with the arm at the side in an adducted and internally rotated position. Phase two, the adhesive or stiffening phase, generally lasts 4 to 12 months. Pain is usually minimal during this phase, although periscapular symptoms may develop from compensatory motion to achieve elevation of the arm. The third phase of the syndrome is the resolution or thawing phase, which may last 5 to 26 months. During this time, pain eases and motion slowly improves, although some patients may improve dramatically over a short period.[176]

In the early stages, any attempts at motion may produce severe pain and associated weakness. The syndrome usually is associated with a prolonged period of immobilization.[177] Pain at night is common, along with an inability to sleep on the associated shoulder; these findings are similar to those of impingement syndrome.

In patients with a history of minimal or no trauma and FSS, a metabolic cause should be excluded. A complete blood cell count, erythrocyte sedimentation rate, serum chemistry, and thyroid function tests are performed as a screening panel. Further testing is performed if results suggest that the patient may have a systemic illness. Plain radiographs should include true anteroposterior, axillary, and scapular Y views of the shoulder. In patients with no underlying detectable illness and a negative workup, a Tc 99m pertechnetate scan may show increased uptake in FSS, but more important, it is used to exclude occult lesions or metastasis.[178]

A literature review reveals a multitude of treatment options, along with significant deficits on accurate reporting of disease staging with response to treatment.[179]

Treatment of FSS is mainly conservative and consists of intra-articular injections, application of heat, gentle stretching, NSAIDs, and modalities such as transcutaneous electrical nerve stimulation. The disease usually is self-limited, and after the painful phase it is not severely disabling. Communication between the physician and the patient, together with a thorough explanation of the condition, is essential, because resolution of the syndrome occurs slowly. Closed manipulation and surgery (open and arthroscopic) are reserved for patients whose condition is recalcitrant to conservative measures or for whom the diagnosis is in question. Paramount in the prevention of FSS is avoiding overimmobilization with a minor shoulder injury, in addition to careful identification of patients at risk for FSS.

Fareed and Gallivan[180] reported good results with hydraulic distention of the glenohumeral joint using local anesthetic agents. Rizk and associates[181] conducted a prospective, randomized study to assess the effects of steroid or local anesthetic injection in 48 patients with FSS. No significant difference in outcome was noted between persons who received intrabursal or intra-articular injection. Steroid with lidocaine offered no advantage compared with lidocaine alone in restoring shoulder motion. However, transient pain relief occurred in two-thirds of patients treated with steroids.[181]

General anesthesia occasionally is indicated for closed manipulation. Hill and Bogumill[182] reported the results of manipulation of 17 frozen shoulders in 15 patients who did not respond to physical therapy. On average, 78% of persons who were working before their shoulder problems returned to work 2.6 months after manipulation. Investigators concluded that manipulation allowed patients to return to a normal lifestyle and to work sooner than the reported natural history of the condition.[182] Surgical intervention for adhesive capsulitis should be limited to treatment of an underlying problem, such as calcific tendinitis or an impingement syndrome.

## Glenohumeral Instability

Glenohumeral instability is a pathologic condition that manifests as pain associated with excessive translation of the humeral head on the glenoid during shoulder motion. Instability can range from excessive laxity with episodes of subluxation to frank dislocation of the joint. Traumatic dislocation of the glenohumeral joint reveals characteristic clinical and radiographic findings that are beyond the scope

of this chapter and have been reviewed in detail elsewhere.[183] The most common type of instability is anterior, although posterior and multidirectional laxity of the shoulder is increasingly recognized as a cause of shoulder pain. Anterior dislocation usually occurs with the arm in an abducted and externally rotated position, and the diagnosis is usually obvious. Posterior dislocation is frequently associated with convulsive disorders or unusual trauma with the arm in a forward flexed and internally rotated position. The diagnosis is often missed and should always be suspected in the patient who is unable to rotate the arm externally after trauma.

Recurrent subluxation without dislocation may be difficult to diagnose and may mistakenly be identified as impingement with chronic cuff tendinitis. An athlete whose sport entails overhead actions may experience repetitive stresses to the shoulder, causing microtrauma to the static stabilizers. Jobe and colleagues[18] described a syndrome of shoulder pain in athletes who engage in overhead activities or throwing that manifests as impingement but is caused by anterior subluxation of the joint, with the humeral head impinging on the anterior aspect of the coracoacromial arch. Fu and co-workers[184] underscored this distinction by dividing the causes of rotator cuff tendinitis into primary impingement of the tendon on the coracoacromial arch and anterior subluxation with secondary impingement in young athletes performing overhead movements. Walch and colleagues[185] described intra-articular impingement between the undersurface of the rotator cuff (supraspinatus and infraspinatus) and the posterior superior glenoid rim and labrum. This "internal impingement" usually is observed in athletes who engage in overhead activities and have subtle anterior glenohumeral instability, and it results in tendinitis or partial tears of the rotator cuff (see Figure 46-16).

The diagnosis of glenohumeral instability with subluxation in one or multiple directions is made with the combination of a detailed history and physical examination and the use of adjuncts, such as arthrography, CT, MRI, and arthroscopy with examination under the effects of anesthesia. The syndrome of multidirectional instability has been recognized in patients with symptomatic inferior instability, in addition to anterior or posterior instability. Approximately 50% of affected patients have evidence of generalized laxity. Frequently, the syndrome occurs in young athletic patients who are loose jointed, in particular in the dominant arm of pitchers, racket sports players, and swimmers. In these types of athletes, repetitive microtrauma may cause stretching of the shoulder, resulting in a large capsular pouch without labral detachment. A traumatic event may damage the shoulder, resulting in the syndrome of multidirectional instability and a Bankart lesion.[186]

The most common manifestation in these patients is pain, which often is mistakenly considered to be rotator cuff tendinitis. The patient may relate a history of minor trauma causing acute pain and a "dead arm" syndrome lasting minutes or hours. Other associated symptoms include a sense of instability, weakness, and radicular symptoms suggestive of neuropathy. Few or no positive physical findings may be associated with chronic subluxation or multidirectional instability. The patient may have signs of generalized ligamentous laxity, and pain may be reproduced by subluxating the glenohumeral joint in multiple directions. One particularly helpful sign of inferior laxity is the sulcus sign, which refers to the subacromial indentation that occurs when longitudinal traction is applied to the humerus with the arm at the side. This sign occurs with inferior translation of the humeral head. Because this syndrome frequently occurs in athletes with highly developed musculature around the shoulder girdle, physical findings of subluxation may be difficult to reproduce in the office setting.

Plain radiographs are generally normal, although some inferior subluxation may be shown on stress radiographs obtained with the use of weights. Special radiographs, as discussed previously, may show a Bankart lesion (i.e., avulsion of the anterior inferior glenoid rim) or a Hill-Sachs lesion (i.e., osteochondral defect of the posterior humeral head) with subluxation of the humeral head in front of the anterior glenoid rim. CT-arthrography or MRI-arthrography may show increased capsular volume, a labral detachment, or a Hill-Sachs lesion (see Figure 46-9). When surgery is indicated, examination under the effects of anesthesia and shoulder arthroscopy may assist in diagnosing the primary direction of instability in the syndrome of multidirectional instability. In selected patients with traumatic anterior dislocation who have no history of multidirectional instability, arthroscopic stabilization may be performed with stabilization of the capsulolabral complex.

Treatment of patients with chronic subluxation or the syndrome of multidirectional instability is first directed toward prolonged rehabilitation. Activities that stress the shoulder and produce symptoms are avoided. Strengthening exercises of the shoulder girdle may control symptoms, dynamically stabilizing the glenohumeral joint, and may obviate the need for surgical intervention. If a conservative treatment program fails, surgery is performed on the side associated with the greatest clinical instability. Stabilization is directed toward tightening of the capsular structures to stabilize the glenohumeral joint.[186,187]

## EXTRINSIC OR REGIONAL FACTORS CAUSING SHOULDER PAIN

Because the shoulder girdle connects the thorax with the upper extremity, and because major neurovascular structures pass in proximity to the joint, shoulder pain is a hallmark of many nonarticular conditions.

### Cervical Radiculopathy

Cervical disease may manifest with associated shoulder pain. The area of referred pain has a dermatomal pattern, consistent with the distribution of dermatomal nerve roots. Isolation of the pain usually defines the exact location of associated cervical disease. Pain can be differentiated from shoulder pain on the basis of history, physical examination, EMG, cervical radiographs, and myelography or MRI when indicated. Because conditions causing cervical neck pain and conditions causing shoulder pain, such as calcific tendinitis and cervical radiculopathy, may co-exist, it often is difficult to distinguish which lesion is responsible for the symptoms. These conditions often can be differentiated by injection of local anesthetics to block certain components of the pain.

The thoracic outlet is an interval created by the anterior and middle scalene muscles and the first rib through which the brachial plexus and vessels pass to the arm. In thoracic outlet syndrome, compression of these nerves and vessels often manifests as vague shoulder pain with numbness of the ipsilateral fourth and fifth digits. Cervical rib or hypertrophy of the scalene muscles can be related to the onset of pain.[188-190] The occurrence of pain also has been related to scapular ptosis, poor posture, and clavicular fracture with malunion or copious formation of callus.

## Brachial Neuritis

In the 1940s, Spillane[191] and Parsonage and Turner[192,193] described a painful condition of the shoulder associated with limitation of motion. As pain subsided and motion improved, muscle weakness and atrophy became apparent. The deltoid, supraspinatus, infraspinatus, biceps, and triceps are the most frequently involved muscles,[194] although diaphragmatic paralysis also has been reported.[193,195] The cause is unclear, but the clustering of cases suggests a viral or postviral syndrome.[192,193] Occasionally, an associated influenza-like syndrome or previous vaccination has been reported.[194]

Hershman and colleagues[196] described acute brachial neuropathy in athletes. Findings that suggest an acute brachial neuropathy include acute onset of pain without trauma; persistent, severe pain that continues despite rest; and patchy neurologic signs. The diagnosis is confirmed by EMG and nerve conduction studies.[196] The prognosis for recovery is excellent, although full recovery may take 2 to 3 years. Tsairis and associates[197] reported 80% recovery within 2 years and more than 90% recovery by the end of 3 years.

## Nerve Entrapment Syndromes

Peripheral compression neuropathies of the upper extremities may produce referral pain to the shoulder. Distant compression neuropathies, such as carpal tunnel (median nerve) and cubital tunnel (ulnar nerve) syndromes, may manifest with concomitant and separate shoulder impingement with rotator cuff disease. Associated numbness and paresthesias with mapping of the dermatomal distribution and with peripheral neuropathy often direct the examiner to the appropriate diagnosis. Patients often give a history of dropping objects and a feeling of clumsiness with the affected hand. A Tinel sign may be elicited over the region of entrapment at the elbow or wrist. Provocative maneuvers such as Phalen's test may be positive and usually indicate median nerve compression at the wrist. Diminished vibratory sensation is an early finding in the disease and is easily reproducible,[198,199] whereas decreased two-point discrimination and intrinsic atrophy are late findings of peripheral compression neuropathy.[198]

The diagnosis usually can be made by clinical examination with exclusion of other possible causes. EMG and nerve conduction velocity tests may reveal slowed conduction and latency at appropriate compression points to aid in diagnosis. Spinal accessory nerve injury with subsequent denervation of the trapezius may cause weakness and pain in the shoulder consistent with impingement. The injury can occur from traction injury to the neck or a direct blow or pressure to the base of the neck. Iatrogenic nerve injury may result from surgical procedures on the neck such as lymph node biopsy.[200] The injury produces weakness in shoulder abduction with associated pain that radiates from the neck into the trapezius and shoulder. Subsequent atrophy of the trapezius may lead to dyssymmetry and ptosis of the involved shoulder, with narrowing of the supraspinatus outlet and secondary impingement with shoulder pain. Definitive diagnosis can be made by EMG examination.

Early treatment is conservative. If return of function is not evident at 6 months, surgical exploration of the nerve with possible tendon transfers may be indicated.[201]

Injury to the long thoracic nerve (cervical fifth, sixth, and seventh roots) can lead to scapular winging. The resultant scapular dysrhythmia and weakness can lead to a painful shoulder that may mimic rotator cuff disease.[200] Patients also report pain and discomfort with active forward flexion of the shoulder. Patients who remain symptomatic after conservative treatment may require surgery for scapulothoracic fusion or tendon transfer with use of the pectoralis major or minor to stabilize the scapula.[202,203]

In quadrilateral space syndrome, the axillary nerve is compressed by fibrous bands in the quadrilateral space.[200,204,205] This syndrome typically occurs when the arm is held in abduction and external rotation, with subsequent tightening of fibrous bands across the nerve.[206] It is most commonly seen in the dominant shoulder of young athletic persons such as pitchers, tennis players, and swimmers who function with an excessive amount of overhead activity. Pain may occur throughout the shoulder girdle and may radiate down the arm in a nondermatomal pattern. Findings of neurologic and EMG testing may be normal. Diagnosis often is made by an arteriogram of the subclavian artery. A positive arteriogram reveals compression of the posterior humeral circumflex artery as it traverses the quadrangular space when the arm is in the abducted and externally rotated position. Surgical intervention may be required to release the fibrotic bands or the tendon of the teres minor if the patient does not respond to conservative treatment.[200,207]

Suprascapular nerve entrapment syndrome can be caused by a traction lesion resulting from repetitive overhead activities, a compression lesion, or both, involving the nerve; it is caused by tethering of the nerve at the suprascapular notch by the suprascapular ligament or at the spinoglenoid notch by the transverse ligament. Suprascapular nerve entrapment syndrome also can result from direct compression of a space-occupying lesion, such as a ganglion or a lipoma. Rengachary and co-workers[208] described variations in size and shape of the suprascapular notch that may predispose the nerve to entrapment. Several authors have noted an association of suprascapular neuropathy with massive rotator cuff tears, presumably resulting from a traction injury to the nerve.[209,210]

The resulting suprascapular neuropathy produces pain in the posterolateral aspect of the shoulder that may radiate into the ipsilateral extremity, shoulder, or side of the neck. Although this condition is uncommon, it can have a prolonged and disabling course when it is not diagnosed. Because the suprascapular nerve has no cutaneous innervation, no numbness, tingling, or paresthesias are associated

with this condition. Weakness is usually noted in abduction and external rotation, and significant atrophy is often observed at diagnosis. The pain frequently is described as a deep burning or aching that can be well localized and often can be elicited by palpation over the region of the suprascapular notch. Any activity that brings the scapula forward, such as reaching across the chest, may aggravate the pain.[211] The location of pain and other symptoms can mimic more common entities, such as impingement, rotator cuff disease, cervical disk disease, brachial neuropathy, biceps tendinitis, thoracic outlet syndrome, AC disease, and instability of the shoulder.[212]

Fritz and colleagues[213] reported the efficacy of MRI in the diagnosis of suprascapular nerve entrapment as a result of space-occupying lesions. Definitive diagnosis is made with EMG and nerve conduction studies. EMG changes usually reveal spontaneous activity in the muscle at rest and fibrillations indicating motor atrophy and denervation. Nerve conduction studies may reveal slowing across the site of entrapment. As with axillary nerve entrapment, the syndrome is often associated with young, athletic persons who engage in excessive overhead activity.[214] It also has been associated with trauma.[212,215,216]

Lack of consensus continues regarding the optimal treatment of suprascapular neuropathy.[1,212,214,217-219] Post and Grinblat[217] reported good to excellent results with surgical treatment in 25 of 26 cases. No difference in residual atrophy and in strength deficits has been shown, however, for operative and nonoperative treatments. Ferretti and co-workers[214] evaluated 96 top-level volleyball players from the 1985 European Championships and found that 12 had isolated suprascapular neuropathy with atrophy of the infraspinatus of the dominant shoulder. All players were unaware of any impairment, however, and played without limitations. After a space-occupying lesion has been excluded, a 6-month trial of conservative treatment may be indicated for some persons. If the entrapment does not improve or if symptoms worsen with conservative treatment, surgical decompression for pain relief is warranted; however, resolution of atrophy and strength gains can vary.[212]

## Sternoclavicular Arthritis

Occasionally, traumatic, nontraumatic, or infectious conditions can cause pain in the area of the sternoclavicular joint (see Figure 46-1). The most common problem involves ligamentous injury and painful subluxation or dislocation, which can be diagnosed by palpable instability and crepitus over the sternoclavicular joint. Radiographic sternoclavicular views may show dislocation.[220]

Inflammatory arthritis of the sternoclavicular joint has been associated with RA, psoriatic arthritis, ankylosing spondylitis, and septic arthritis. The association of palmoplantar pustulosis with sternoclavicular arthritis has been reported.[221] Seven of 15 patients who underwent biopsy for this condition had cultures positive for *Propionibacterium acnes*, suggesting an infectious origin of the condition.[221]

Two other conditions involving the sternoclavicular joint are Tietze's syndrome, a painful, nonsuppurative swelling of the joint and adjacent sternochondral junctions, and Friedrich's syndrome, a painful osteonecrosis of the sternal end of the clavicle.[4] Condensing osteitis of the clavicle is a rare benign idiopathic lesion of the medial one-third of the clavicle. This condition, which is better described as aseptic enlarging osteosclerosis of the clavicle, is most commonly seen in middle-aged women and manifests as a tender swelling over the medial one-third of the clavicle.[222]

## Reflex Sympathetic Dystrophy

Since its original description by Mitchell[223] in 1864, reflex sympathetic dystrophy (RSD) has remained a poorly understood and frequently overlooked condition. Its cause is unknown but may be related to sympathetic overflow or short-circuiting of impulses through the sympathetic system. Any clinician who deals with painful disorders must be familiar with the diagnosis and treatment of this condition. Bonica's[224] excellent review covers the clinical presentation, various stages of the disease, and the importance of early intervention to ensure a successful outcome.

RSD has been called causalgia, shoulder-hand syndrome, and Sudeck's atrophy, which has caused some confusion. It is generally associated with minor trauma and is to be differentiated from causalgia, which involves trauma to major nerve roots.[223] RSD is divided into three phases, which are important in determining appropriate treatment.[224] Phase one is characterized by sympathetic overflow with diffuse swelling, pain, increased vascularity, and radiographic evidence of demineralization. If left untreated for 3 to 6 months, the condition may progress to phase two, which is characterized by atrophy. The extremity may now be cold and shiny, with atrophy of the skin and muscles. Phase three refers to progression of trophic changes, with irreversible flexion contracture and a pale, cold, painful extremity. It has been speculated that phase one is related to peripheral short-circuiting of nerve impulses, phase two represents short-circuiting through the internuncial pool in the spinal cord, and phase three is controlled by higher thalamic centers.[224,225]

Steinbrocker[226] reported that recovery is possible as long as vasomotor activity with swelling and hyperemia is evident. After the trophic phase two or three is established, the prognosis for recovery is poor. Prompt recognition of the syndrome is important because early intervention to control pain is mandatory. Careful supervision and reassurance are crucial because many of these patients are emotionally labile as a result of the pain or an underlying problem. The syndrome may be reversed to a remarkable degree by a sympathetic block. Patients who receive transient relief from sympathetic blockade may be helped by surgical sympathectomy.

## Neoplasms

Primary and metastatic neoplasms may cause shoulder pain by direct invasion of the musculoskeletal system or by compression with referred pain.[2,227] Primary tumors are more likely to occur in younger persons. More common lesions have a typical distribution, such as the predilection of a chondroblastoma for the proximal humeral epiphysis or an osteogenic sarcoma for the metaphysis.[228] The differential diagnosis of spontaneous onset of shoulder pain in older persons should include metastatic lesions and myeloma.

Neoplasms are best identified by plain radiographs, MRI, Tc 99m MDP scintigraphy, and CT.

Neoplasms also may involve the shoulder region through metastases to the region. An associated history of carcinomas should alert the examiner to the possibility of a bone tumor, especially in patients who have had malignancies with a predilection for metastasis to bone (e.g., thyroid, renal, lung, prostate, and breast malignancies). Pain often is present at rest and is exacerbated at night. Atypical pain distribution that is not relieved by injection without specific dermatomal distribution should alert the examiner to other underlying possibilities. Plain radiographs should be evaluated thoroughly for any cortical destruction and for lytic lesions.

Pancoast syndrome or apical lung tumor may manifest as shoulder pain or cervical radiculitis caused by invasion of the brachial plexus or invasion of C8 or T1 roots.[229-231] With invasion of the cervical sympathetic chain, the patient also may experience Homer's syndrome.

## Miscellaneous Conditions

With increasing numbers of patients undergoing long-term maintenance hemodialysis, a shoulder pain syndrome known as dialysis shoulder arthropathy has been described. This syndrome consists of shoulder pain, weakness, loss of motion, and functional limitation. The cause and pathogenesis of this syndrome are unclear, although rotator cuff disease, pathologic fracture, bursitis, and local amyloid deposition have been implicated as causative factors.[232] Surgical or necropsy data are insufficient to confirm a specific diagnosis. Patients generally respond poorly to local measures of injection, application of heat, and NSAIDs, but their condition may improve with correction of underlying metabolic disorders, such as osteomalacia and secondary hyperparathyroidism.

In patients older than 50 years who have bilateral shoulder pain and stiffness, polymyalgia rheumatica should be considered as a diagnosis. This condition is twice as common among females and is almost exclusively found in white persons.[233] Most patients have sedimentation rates greater than 40 mm/hr and respond to low doses of corticosteroids.[234]

CHAPTER 47

# Low Back Pain

Rajiv Dixit

## KEY POINTS

- Low back pain (LBP) affects as many as 80% of individuals, and degenerative changes of the lumbar spine is the most common cause.
- More than 90% of these patients are mostly pain free within 8 weeks.
- The initial evaluation should focus on identification of the few patients with neurologic involvement, fracture, or possible systemic disease (infection, malignancy, or spondyloarthritis) because they may need urgent or specific intervention.
- Psychosocial and other factors that predict risk of chronic disabling LBP should be assessed.
- Imaging is rarely indicated in the absence of significant neurologic involvement, trauma, or suspicion of systemic disease.
- Imaging abnormalities, often the result of age-related degenerative changes, should be carefully interpreted because they are frequently present in asymptomatic individuals.
- A precise pathoanatomic diagnosis with identification of the pain generator cannot be made in up to 85% of patients.
- Persistent LBP should be treated with an individually tailored program that includes analgesia, core strengthening, stretching, aerobic conditioning, loss of excess weight, and patient education.
- Intensive interdisciplinary rehabilitation with an emphasis on cognitive-behavioral therapy should be strongly considered if conservative measures fail.
- There is no evidence for the effectiveness of epidural corticosteroid injections in patients without radiculopathy secondary to disk herniation.
- A large number of injection techniques, physical therapy modalities, and nonsurgical interventional therapies lack evidence of efficacy.
- The major indication for back surgery is presence of a serious or progressive neurologic deficit.
- In the absence of neurologic deficits, back surgery, especially spinal fusion for degenerative changes, has not been shown to be more effective than conservative care.

## EPIDEMIOLOGY

Low back pain (LBP) is one of the most common conditions encountered in clinical medicine. It affects the area between the lower rib cage and gluteal folds.

An estimated 65% to 80%[1] of the population will experience LBP during their lifetime. LBP is the most prevalent chronic pain syndrome and the leading cause of limitation of activity in patients younger than 45 years. It is also the second most frequent reason for a visit to the physician's office and the third most common reason for surgery.[2] The prevalence of LBP increases with age until between 60 and 65 years, then gradually declines.[3] LBP is more common in women.

The natural history of back pain, especially the duration and chronicity, is somewhat controversial. Regardless, studies show that pain and function improve substantially in most patients within 1 month,[4] and more than 90% are better at 8 weeks.[5] These patients, however, remain susceptible to future relapses that also tend to be brief. Chronic LBP develops in the remaining 7% to 10%, and these individuals are largely responsible for the high costs associated with LBP. Expenditures on spinal conditions in the United States have significantly increased in recent years, despite little change in the health status among people who experience these conditions.[6] The general consensus is that approximately $90 billion is spent on the diagnosis and management of LBP, and an additional $10 to $20 billion is attributed to economic loses in productivity each year.[6-8]

A number of risk factors have been associated with LBP, including heredity, psychosocial factors, heavy lifting, obesity, pregnancy, weaker trunk strength, and cigarette smoking.[9] Persistence of disabling LBP has been associated with the presence of maladaptive pain coping behavior, nonorganic signs, functional impairment, poor general health status, and psychiatric comorbidities.[10]

## ANATOMY

The lumbar spine is composed of five vertebrae. Each vertebra consists of a body anteriorly and a neural arch that encloses the spinal canal posteriorly (Figure 47-1). Their cartilaginous end plates cover the superior and inferior surfaces of the vertebral body.

Adjacent vertebrae are united by an intervertebral disk. The outer circumference of the disk is made up of concentric layers of dense, tough fibrous tissue, the annulus fibrosus.

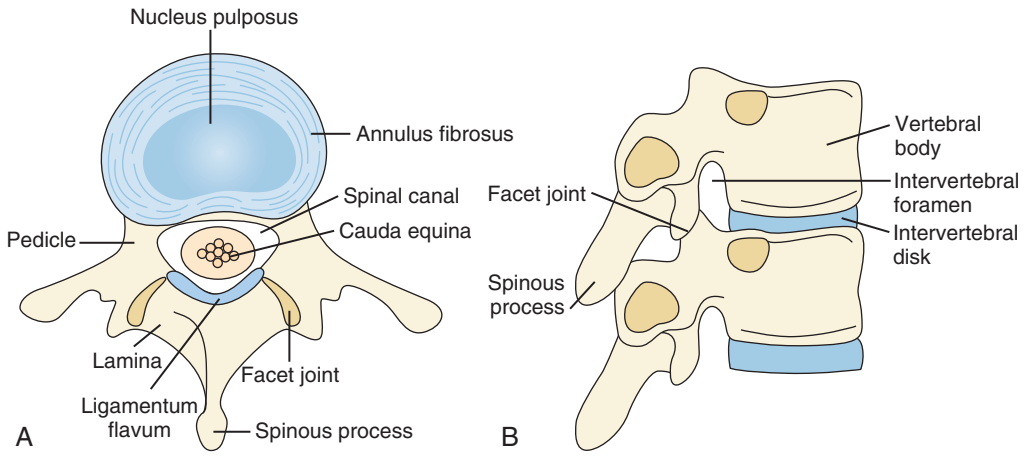

**Figure 47-1** Anatomy of the lumbar spine. **A,** Cross-sectional view through a lumbar vertebra. **B,** Lateral view of the lumbar spine.

The annulus encloses a shock-absorbing gelatinous nucleus pulposus. In addition to the anteriorly placed diskovertebral joint (formed by the intervertebral disk and adjacent vertebrae), at each level of the lumbar spine, there are two posterolaterally placed synovial facet (apophyseal) joints. These are formed by articulation of the superior and inferior articular processes of adjacent vertebrae.

The vertebral column is further stabilized by ligaments and paraspinal muscles (erector spinae, trunk, and abdominal muscles). The anterior and posterior longitudinal ligaments run the length of the spinal column. They anchor the anterior and posterior vertebral body surfaces and intervertebral disks. The ligamentum flavum interconnects the laminae, whereas the interspinous and supraspinous ligaments interconnect the spinous processes. The intertransverse ligaments interconnect the transverse processes.

The sacroiliac joints join the spinal column to the pelvis. The anterior and inferior part of the joint is lined with synovium, whereas the posterior and superior part is fibrous. There is little or no movement at the sacroiliac joint.

The spinal canal in the lumbar region contains the cauda equina (the bundle of lumbar and sacral nerve roots that occupy the vertebral canal below the cord), blood vessels, and fat. Because the spinal cord ends at the L1 level, cord compression is generally not a feature of lumbar pathology. At each level a pair of nerve roots leaves the spinal canal and exits through the intervertebral foramina.

## CLINICAL EVALUATION

LBP has a large number of causes, and the spectrum of clinical presentation is broad. Many individuals will have self-limited episodes of acute LBP that resolve without specific treatment, whereas others may be seen with recurrent or chronic LBP. A thorough history is the most important part of the clinical evaluation of these patients. Imaging is often unnecessary.

### History

The major focus in the initial evaluation of a patient with LBP is to identify the small fraction[11] (<5%) of patients who may have neural compression, fracture, or underlying systemic disease (infection, malignancy, or spondyloarthritis) as the cause of back pain. These patients require early diagnostic testing (mostly imaging) and may require specific treatment (e.g., antibiotics for vertebral osteomyelitis) or urgent treatment (e.g., surgical decompression in a patient with major or progressive neural compression). As such, clues to the presence of the previously mentioned conditions[12-14] (Table 47-1), often referred to as "red flags," should be carefully sought. The prevalence of serious spine disorders is low and the sensitivity and specificity of most red flags is modest. As a result, recent studies have highlighted the limited predictive value of most red flags, and suggested that performing imaging with the presence of any red flag would result in unnecessarily high rates of imaging. It has therefore been suggested that use of imaging should be guided by the full clinical picture and observations during

**TABLE 47-1** Red Flags for Potentially Serious Underlying Causes of Low Back Pain

| |
|---|
| **Spinal Fracture** |
| Significant trauma |
| Prolonged glucocorticoid use |
| Age >50 yr |
| **Infection or Cancer** |
| History of cancer |
| Unexplained weight loss |
| Immunosuppression |
| Injection drug use |
| Nocturnal pain |
| Age >50 yr |
| **Cauda Equina Syndrome** |
| Urinary retention |
| Overflow incontinence |
| Fecal incontinence |
| Bilateral or progressive motor deficit |
| Saddle anesthesia |
| **Spondyloarthritis** |
| Severe morning stiffness |
| Pain improves with exercise, not rest |
| Pain during second half of night |
| Alternating buttock pain |
| Age <40 yr |

time, rather than by the uncritical use of individual red flags. The presence of multiple red flags generates higher predictive values.[15] It is also important to look for any social or psychological distress, such as job dissatisfaction, pursuit of disability compensation, and depression, that may amplify or prolong the pain.[14]

Mechanical LBP is due to an anatomic or functional abnormality in the spine that is not associated with inflammatory or neoplastic disease. It typically increases with physical activity and upright posture and tends to be relieved by rest and recumbency. More than 95% of LBP is mechanical,[11] and degenerative change in the lumbar spine is the most common cause of mechanical LBP.[12] Severe and acute mechanical LBP in a post-menopausal woman would suggest a vertebral compression fracture secondary to osteoporosis. Nocturnal pain suggests the possibility of underlying infection or neoplasm as the cause of LBP.

Inflammatory LBP,[16] as seen in the spondyloarthritides, is more common in men younger than 40 years. It is associated with marked morning stiffness that usually lasts for more than 30 minutes. The pain frequently improves with exercise but not with rest. Pain is often worse during the second half of the night, and some patients complain of alternating buttock pain.

It is important to ask the patient if the back pain radiates into the lower extremities, suggesting pseudoclaudication (neurogenic claudication) secondary to spinal stenosis or sciatica (usually secondary to a herniated disk or spinal stenosis). Young adults are more likely to be seen with the clinical syndrome of disk herniation, and elderly patients are more likely to be seen with the clinical features of spinal stenosis. Sciatica results from nerve root compression and produces pain in a dermatomal (radicular) distribution, usually to the level of the foot or ankle. The pain is often lancinating, shooting, and sharp in quality. It is frequently accompanied by numbness and tingling and may be accompanied by sensory and motor deficits. Sciatica resulting from disk herniation typically increases with cough, sneezing, or the Valsalva maneuver. Sciatica should be differentiated from non-neurogenic sclerotomal pain. This pain can arise from pathology within the disk, facet joint, or lumbar paraspinal muscles and ligaments. Similar to sciatica, sclerotomal pain is often referred into the lower extremities, but unlike sciatica, sclerotomal pain is nondermatomal in distribution, it is usually dull in quality, and the pain usually does not radiate below the knee or have associated paresthesias. Most radiant pain is sclerotomal.[12] Bowel or bladder dysfunction should suggest the possibility of the cauda equina syndrome.

## Physical Examination

A physical examination usually does not lead to a specific diagnosis. Nevertheless, a general physical examination including a careful neurologic examination may help identify those few but critically important cases of LBP that are secondary to a systemic disease or have clinically significant neurologic involvement (see Table 47-1).

Inspection may reveal the presence of scoliosis. This can be either structural or functional. A structural scoliosis is associated with structural changes of the vertebral column and sometimes the rib cage as well. In adults structural scoliosis is usually secondary to degenerative changes, although some adults may have a history of adolescent idiopathic scoliosis. With forward flexion, structural scoliosis persists. In contrast, functional scoliosis, which usually results from paravertebral muscle spasm or leg length discrepancy, usually disappears. A tuft of hair in the lumbar spine region may indicate a congenital structural abnormality such as spina bifida occulta.

Palpation can detect paravertebral muscle spasm. This often leads to loss of the normal lumbar lordosis. Point tenderness on percussion over the spine has sensitivity but not specificity for vertebral osteomyelitis. A palpable step-off between adjacent spinous processes suggests spondylolisthesis.

Limited spinal motion (flexion, extension, lateral bending, and rotation) is not associated with any specific diagnosis because LBP from any cause may limit motion. Range-of-motion measurements, however, can help in monitoring treatment.[9] Chest expansion of less than 2.5 cm has specificity but not sensitivity for ankylosing spondylitis.[16]

The hip joints should be examined for any decrease in range of motion because hip arthritis, which normally causes groin pain, may occasionally refer pain to the back. Trochanteric bursitis with tenderness over the greater trochanter of the femur can be confused with LBP. The presence of more widespread tender points, especially in a female patient, suggests the possibility that LBP may be secondary to fibromyalgia.

A complete neurologic examination should be performed because neurologic abnormalities in the upper extremities, such as hyper-reflexia, may indicate a more proximal etiology of a patient's lower extremity complaints. In patients with a history of LBP that radiates into the lower extremities (sciatica, pseudoclaudication, or referred sclerotomal pain), a straight leg–raising test (Figure 47-2) should be performed. With the patient lying on his or her back, the examiner places the heel in the palm of his or her hand and progressively raises the patient's leg with the knee fully extended. This movement places tension on the sciatic nerve (that originates from L4, L5, S1, S2, and S3) and thereby stretches the nerve roots (especially L5, S1, and S2). If any of these nerve roots is already irritated, such as by impingement from a herniated disk, further tension on the nerve root by straight leg raising will result in radicular pain that extends below the knee. The test is positive if radicular pain is produced when the leg is raised less than 70 degrees. Dorsiflexion of the ankle further stretches the sciatic nerve and increases the sensitivity of the test. Pain

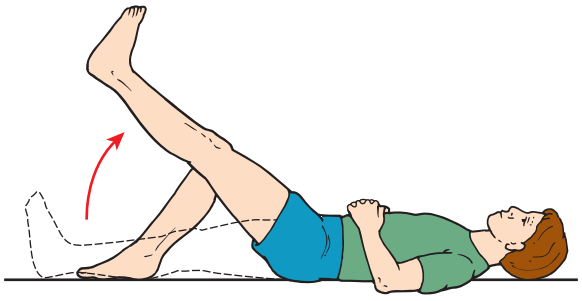

**Figure 47-2** Straight leg–raising test. A very sensitive test for nerve root impingement at the L4-5 or L5-S1 level.

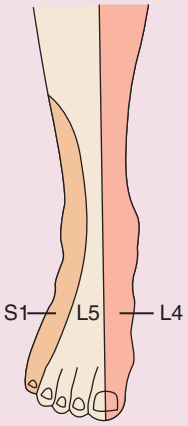

| Lower extremity dermatome | Disk | Nerve root | Motor loss | Sensory loss | Reflex loss |
|---|---|---|---|---|---|
|   | L3-4 | L4 | Dorsiflexion of foot | Medial foot | Knee |
| | L4-5 | L5 | Dorsiflexion of great toe | Dorsal foot | None |
| | L5-S1 | S1 | Plantarflexion of foot | Lateral foot | Ankle |

**Figure 47-3** Neurologic features of lumbosacral radiculopathy.

experienced in the posterior thigh or knee during straight leg–raising is generally from hamstring tightness and does not represent a positive test. The straight leg–raising test is sensitive but not specific for clinically significant disk herniation at the L4-5 or L5-S1 level (the sites of 95% of clinically meaningful disk herniations). False-negative tests are more frequently seen with herniation above the L4-5 level. The straight leg–raising test is usually negative in patients with spinal stenosis. The crossed straight leg–raising test (with sciatica reproduced when the opposite leg is raised) is highly specific but insensitive for a clinically significant disk herniation.[9,14,17,18]

The neurologic evaluation (Figure 47-3) of the lower extremities in a patient with sciatica can identify the specific nerve root involved. The evaluation should include motor testing with focus on dorsiflexion of the foot (L4), great toe dorsiflexion (L5), and foot plantar flexion (S1); determination of knee (L4) and ankle (S1) deep tendon reflexes; and tests for dermatomal sensory loss. The inability to toe walk (mostly S1) and heel walk (mostly L5) indicate muscle weakness. Muscle atrophy can be detected by circumferential measurements of the calf and thigh at the same level bilaterally.[9]

Patients involved with litigation or with psychological distress occasionally exaggerate their symptoms. They may display nonorganic signs where the objective findings do not match the subjective complaints, such as with nonanatomic motor or sensory loss. A number of tests to detect this have been described by Waddell and co-workers.[19] The most reproducible tests are the presence of superficial tenderness, over-reaction during the examination, and observation of a discrepancy in the straight leg–raising test done in the seated and supine positions.

## Diagnostic Tests

### Imaging

There is concern about overuse of lumbar spine imaging, especially in the United States where imaging capacity is high. Indiscriminate spine imaging leads to a low yield of clinically useful findings, a high yield of misleading findings, radiation exposure, and costs.[15] The major function of diagnostic testing, especially imaging, is the early identification of pathology in those few patients who have evidence of a major or progressive neurologic deficit, and those in whom an underlying systemic disease or vertebral fracture is suspected (see Table 47-1). Otherwise, imaging is not required unless significant symptoms persist beyond 6 to 8 weeks. This approach avoids unnecessary early testing because more than 90% of the patients will have largely recovered by 8 weeks.[9,11] Furthermore, neither MRI nor plain radiographs obtained early in the course of LBP evaluation improves clinical outcome, predicts recovery course, or reduces the overall cost of care.[2,20]

A significant problem with all imaging studies is that many of the anatomic abnormalities identified in patients with LBP are also commonly present in asymptomatic individuals and are frequently unrelated to the back pain.[12] Often these abnormalities result from age-related degenerative changes, which begin to appear even in early adulthood and are among the earliest degenerative changes in the body.[21] Although clinically challenging and sometimes impossible, one should refrain from making causal inferences based solely on imaging abnormalities in the absence of corresponding clinical findings because this may lead to unnecessary, invasive, and costly interventions.[22,23]

Given the weak association between imaging abnormalities and symptoms, it is not surprising that in as many as 85% of patients a precise pathoanatomic diagnosis with identification of the pain generator cannot be made.[14] Patients should understand that the reason for imaging is to rule out serious conditions and that common degenerative findings are expected. Ill-considered attempts to make a diagnosis on the basis of imaging studies may falsely reinforce the suspicion of serious disease (leading to "fear avoidance" behavior), magnify the importance of nonspecific findings, and label patients with spurious diagnoses.

Plain radiographs and MRI are the major modalities used in the evaluation of patients with LBP. In patients with

persistent LBP of greater than 6 to 8 weeks' duration despite standard therapies, radiography may be a reasonable first option if there are no symptoms suggesting radiculopathy or spinal stenosis.[24] Standing anteroposterior and lateral views are usually adequate. Oblique views substantially increase radiation exposure and add little new diagnostic information. Gonadal radiation in a woman from a two-view radiograph of the lumbar spine is equivalent to radiation exposure from a chest radiograph taken daily for more than 1 year.[24]

Abnormalities on radiography, such as single-disk degeneration, facet joint degeneration, Schmorl's nodes (protrusion of the nucleus pulposus into the spongiosa of a vertebra), spondylolysis, mild spondylolisthesis, transitional vertebrae (the "lumbarization" of S1 or "sacralization" of L5), spina bifida occulta, and mild scoliosis, are equally prevalent in individuals with and without LBP.[11,12,25]

MRI without contrast is generally the best initial test for patients with LBP who require advanced imaging. It is the preferred modality for the detection of spinal infection and cancers, herniated disks, and spinal stenosis.[11] MRI testing for LBP should largely be limited to patients in whom there is a suspicion of systemic disease (such as infection or malignancy), for the pre-operative evaluation of patients who are surgical candidates on clinical grounds[14,24] (e.g., the presence of a significant or progressive neurologic deficit), or for those patients with radiculopathy who are candidates for epidural corticosteroids.[24] Disk abnormalities are commonly noted on MRI studies but often have little or no relationship with the patient's symptoms. A disk bulge is a symmetric, circumferential extension of disk material beyond the interspace. A disk herniation is a focal or asymmetric extension. Herniations are subdivided into protrusions and extrusions. Protrusions are broad-based, whereas extrusions have a "neck" so that the base is narrower than the extruded material. Bulges (52%) and protrusions (27%) are common in asymptomatic adults, but extrusions are rare.[11] MRI with the intravenous contrast agent gadolinium may be useful for the evaluation of patients with prior back surgery (with no hardware present) to help in the differentiation of scar tissue from recurrent disk herniation.

MRI is generally preferred versus CT scanning in the evaluation of patients with LBP. However, when bone anatomy is critical, CT is superior. Unlike MRI, CT can safely be done in patients with a ferromagnetic implant, although imaging artifacts may make interpretation difficult. CT myelography is therefore sometimes preferred in patients with surgically placed spinal hardware.

Bone scanning is used primarily to detect infection, bony metastases, or occult fractures and to differentiate them from degenerative changes. Bone scans have limited specificity due to poor spatial resolution, and thus abnormal findings often require further confirmatory imaging such as MRI.

### Electrodiagnostic Studies

Electrodiagnostic studies can be helpful in the evaluation of some patients with lumbosacral radiculopathy. The main procedures are electromyography and nerve conduction studies. These studies can confirm nerve root compression and define the distribution and severity of involvement. Whereas studies such as MRI can only provide anatomic information, electrodiagnostic studies provide physiologic information that may support or refute the findings on imaging. Electrodiagnostic testing is therefore mostly considered in patients with persistent disabling symptoms of radiculopathy in which there is discordance between the clinical presentation and findings on imaging. Electromyography and nerve conduction studies can also be helpful in differentiating the limb pain of peroneal nerve palsy or lumbosacral plexopathy from that of L5 radiculopathy. These studies are also useful to evaluate possible factitious weakness. Electrodiagnosis is unnecessary in a patient with an obvious radiculopathy. It should be noted that electromyographic changes depend on the development of muscle denervation following nerve injury and may not be detected for 2 to 3 weeks after the injury. In contrast, nerve conduction tests become abnormal immediately after nerve damage. Another limitation is that electromyographic abnormalities may persist for more than a year following decompressive surgery.[26]

### Laboratory Studies

Laboratory studies are used mostly in identifying patients with systemic causes of LBP. A patient with normal blood cell counts, erythrocyte sedimentation rate, and radiographs of the lumbar spine is unlikely to have underlying infection or malignancy as the cause of LBP.[27]

## DIFFERENTIAL DIAGNOSIS

LBP usually originates from pathology within the lumbar spine or associated muscles and ligaments (Table 47-2). Rarely, pain is referred to the back from visceral disease. In the vast majority of patients with LBP, the pain is

*Related to degenerative changes.

mechanical.[14] Degenerative change in the lumbar spine is the largest contributor to the mechanical causes of LBP[11] (see Table 47-2) and indeed the most commonly identified cause of back pain.

## Lumbar Spondylosis

The current common usage of the term *lumbar spondylosis* incorporates degenerative changes in both the anteriorly placed diskovertebral joints and the posterolaterally placed facet joints.[9] These degenerative or osteoarthritic changes are seen radiographically as disk or joint-space narrowing, subchondral sclerosis, and osteophytosis (Figure 47-4).

Imaging evidence of lumbar spondylosis is common in the general population, increases with age, and may be unrelated to back symptoms. Radiographic abnormalities such as single-disk degeneration, facet joint degeneration, Schmorl's nodes, mild spondylolisthesis, and mild scoliosis are equally prevalent in persons with and without back pain.[28] The situation is further complicated by the observation that patients with severe mechanical LBP may have minimal radiographic changes, and conversely patients with advanced changes may be asymptomatic.

The clinical spectrum of mechanical LBP is wide. Patients may present with acute LBP (with recurrent attacks in some), whereas chronic LBP (often with periods of acute exacerbation) may develop in others. Somatic referral may lead to sclerotomal pain that radiates into the buttocks and lower extremities. Lumbar spondylosis predisposes patients to intervertebral disk herniation, spondylolisthesis, and spinal stenosis. Overall, degenerative changes of the lumbar spine are the most common cause of back pathology and pain.

In some patients with facet joint osteoarthritis the pain may radiate into the buttock and posterior thigh, be alleviated with forward flexion, and be exacerbated by bending ipsilateral to the involved joint (facet syndrome).

The terms internal disk disruption and diskogenic low back pain are used interchangeably and remain controversial diagnoses[17] when diagnosed by provocative diskography. Following contrast injection into several disks in sequence, the radiographic appearance and induced pain at each level are assessed. If injection into a disk reproduces a patient's usual LBP, the test is considered positive. Advocates of this technique interpret a positive diskogram as defining the particular disk as the primary pain generator, and spinal fusion or disk arthroplasty is frequently recommended.[2] However, injection into a disk can simulate the quality and location of pain known not to originate from that disk.[29] Furthermore, diskographic abnormalities and induced pain are frequently seen in asymptomatic persons and, more importantly, the diskogenic pain attributed to disk disruption frequently improves spontaneously.[11,14] Finally, long-term follow-up of patients who have undergone diskography has led to a concern that the procedure itself may lead to accelerated disk degeneration and disk herniation.[30] Therefore the clinical importance and appropriate management of this condition when diagnosed by diskography remains unclear.

Modic changes are signal changes in the vertebral endplate and adjacent bone marrow that are commonly reported following lumbar MRI. Modic type I changes are secondary

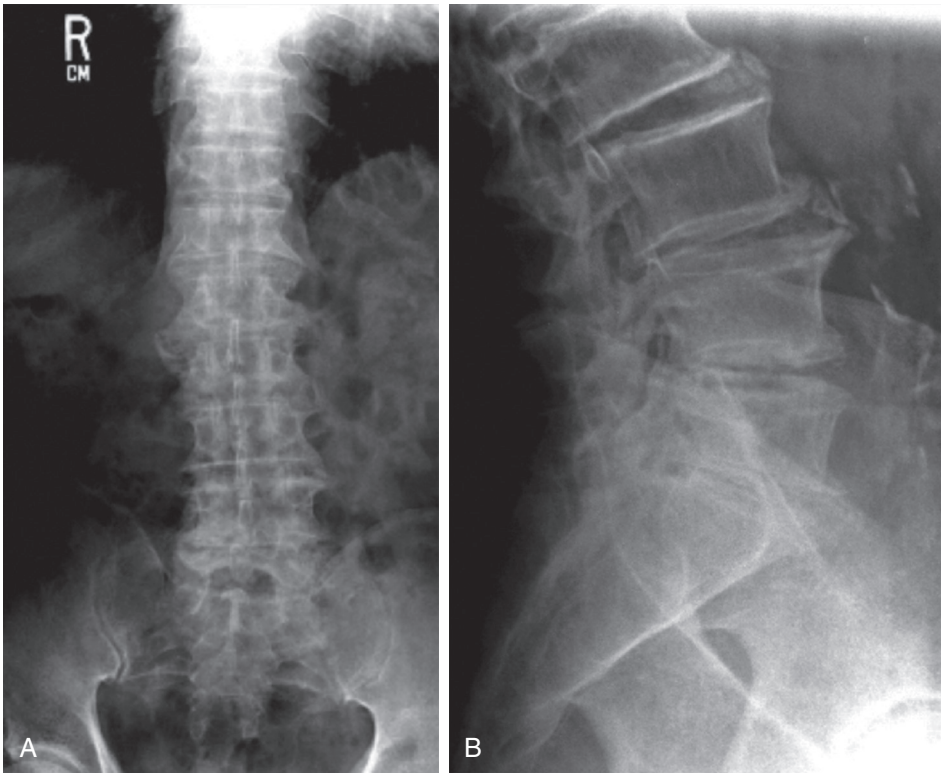

**Figure 47-4** Lumbar spondylosis. Anteroposterior **(A)** and lateral **(B)** radiographs of the lumbar spine show the cardinal features of disk-space narrowing, marginal osteophytes, and end-plate sclerosis. *(Courtesy Dr. John Crues, University of California, San Diego.)*

to marrow edema, Modic type II changes represent fatty replacement of marrow, and Modic type III changes reflect subchondral bone sclerosis.[31,32] The prevalence of these changes, which may progress or regress over time, increases with age and appears to be associated with degenerative disk changes.[33] Modic changes are present in 20% to 40% of LBP patients but may be seen in as many as 10% of asymptomatic adults.[31,32] The clinical usefulness with regard to selecting treatment options of these signal changes are unclear.[34]

Focal high signal in the posterior annulus fibrosus as seen on T2-weighted MRI images, sometimes referred to as a *high-intensity zone*, is believed to represent tears in the annulus fibrosus and to correlate with positive findings on provocative diskography.[11] The high prevalence of high-intensity zones in asymptomatic individuals limits its clinical value.[35]

Spinal instability is seen in some patients with lumbar spondylosis. It is identified by demonstrating abnormal vertebral motion (anteroposterior displacement or excessive angular change of adjacent vertebrae) on lateral radiographs in flexion and extension. However, such spinal motion may be seen in asymptomatic persons and its natural history and relationship to the causation of LBP is unclear. Thus the diagnosis of spinal instability (in the absence of fractures or spondylolisthesis) as a cause of LBP and its treatment by spinal fusion remains controversial.

## Disk Herniation

Intervertebral disk herniation occurs when the nucleus pulposus in a degenerated disk prolapses and pushes out the weakened annulus, usually posterolaterally. Imaging evidence of disk herniation has a high prevalence in the general population. One study found MRI evidence of disk herniation in 27% of asymptomatic individuals.[36] Occasionally, however, the herniated disk can cause nerve root impingement that leads to lumbosacral radiculopathy (Figures 47-5 and 47-6). A herniated intervertebral disk is the most common cause of sciatica in young adults.[11]

The lumbosacral spine is susceptible to disk herniation because of its mobility. Seventy-five percent of flexion and extension occurs at the lumbosacral joint (L5-S1), and 20% occurs at L4-5[37] (with more torsion at the L4-5 level). Probably related to this, 90% to 95% of clinically significant compressive radiculopathies occur at these two levels.[14]

The frequency of disk herniation increases with age. The peak frequency of herniation at the L5-S1 and L4-L5 levels is between the ages of 44 and 50 years, with a progressive decline in frequency thereafter.[38]

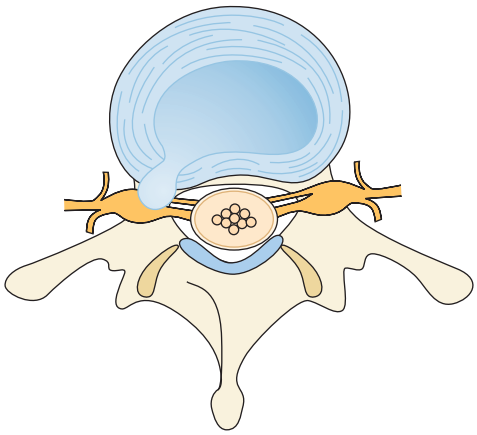

**Figure 47-5** Schematic drawing showing posterolateral disk herniation resulting in nerve root impingement.

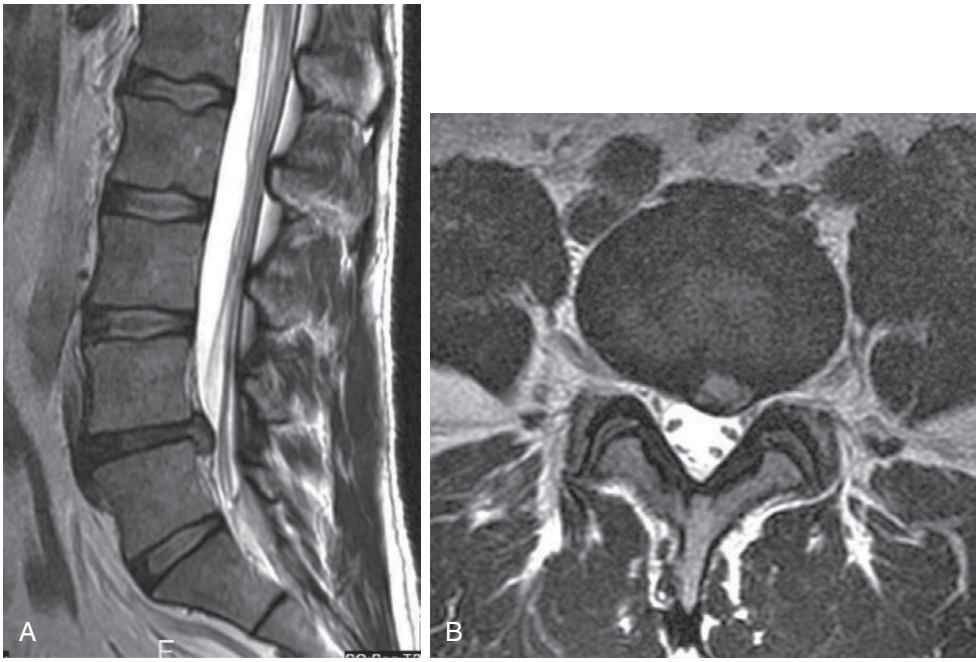

**Figure 47-6** Lumbar disk extrusion. **A,** The sagittal T2-weighted magnetic resonance image shows an extruded disk at the L4-5 level. **B,** The axial image through the L4-5 level shows disk extrusion to the left side of the neural canal and compressing the exiting L5 nerve root against the left lamina. *(Courtesy Dr. John Crues, University of California, San Diego.)*

The genesis of sciatica is felt to have both a mechanical (disk material impinging on a nerve root) and biologic component. Inflammation, vascular invasion, immune responses, and an array of cytokines have been implicated.

The clinical features of disk herniation resulting in lumbosacral radiculopathy have already been discussed (see history, physical examination, and Figure 47-3). It should be noted that immediate imaging is unnecessary in patients without a clinically significant neurologic deficit and no red flags to suggest an underlying systemic pathology (see Table 47-1). L1 radiculopathy is rare and patients are seen with symptoms of pain, paresthesias, and sensory loss in the inguinal region.[39] L2, L3, and L4 radiculopathies are uncommon and more likely to be seen in older patients with lumbar spinal stenosis.

The natural history of disk herniation is favorable, with progressive improvement expected in most patients. Sequential MRI studies reveal that the herniated portion of the disk regresses with time, and there is partial or complete resolution in two-thirds of cases after 6 months.[14,40] Only approximately 10% of patients have sufficient pain after 6 weeks of conservative care, and for this group, decompressive surgery is considered.[14] Even a sequestered fragment (piece of herniated material that breaks off and is free in the epidural space) tends to be reabsorbed with time.[41]

Rarely, a large midline disk herniation, usually L4-5,[12] compresses the cauda equina, resulting in cauda equina syndrome. Patients usually are seen with LBP, bilateral radicular pain, and bilateral motor deficits with leg weakness. Physical examination findings are often asymmetric. Sensory loss in the perineum (saddle anesthesia) is common, and urinary retention with overflow incontinence is frequently present.[14] Fecal incontinence may also occur. The spectrum of signs and symptoms are presented in Table 47-3. Other causes of cauda equina syndrome include neoplasia, epidural abscess, hematoma, and rarely lumbar spinal stenosis. Cauda equina syndrome is a surgical emergency because neurologic results are affected by the time to decompression.[9] Whenever possible, the cauda equina syndrome should be recognized before established incontinence because, once urinary retention has occurred, the prognosis is worse.[42]

## SPONDYLOLISTHESIS

Spondylolisthesis is the anterior displacement of a vertebra on the one beneath it. There are two major types: isthmic and degenerative.

Isthmic spondylolisthesis (Figure 47-7), most commonly seen at the L5-S1 level, is caused by bilateral spondylolysis. Spondylolysis is a defect in the pars interarticularis that is most commonly seen at L5. It is typically a fatigue fracture acquired early in life that is more commonly seen in boys. Based on CT imaging the prevalence of spondylolysis in adults is 11.5%, nearly twice the prevalence of plain radiograph–based studies.[43] Spondylolysis progresses to spondylolisthesis in approximately 15% of patients.[44]

Degenerative spondylolisthesis develops in some patients with severe degenerative changes with subluxation at the facet joints allowing anterior or posterior movement of one

vertebra over another. It is usually seen in an older age group (typically older than 60 years), is more common in women, most frequently involves the L4-5 level, and rarely exceeds 30% of vertebral width.[12]

Most patients, especially those with a minor degree of spondylolisthesis, are asymptomatic. Some may complain of an aching mechanical LBP. Neurologic complications may occur in some with greater degrees of spondylolisthesis. Nerve root impingement is more likely to be seen in patients with isthmic spondylolisthesis (especially L5 nerve root), whereas in degenerative spondylolisthesis the more likely clinical presentation is of spinal stenosis. Rarely, extreme slippage results in cauda equina syndrome. In view of its potential dynamic nature, spondylolisthesis may be missed if standing radiographs are not obtained.

## SPINAL STENOSIS

Lumbar spinal stenosis is defined as a narrowing of the central spinal canal, its lateral recesses, and neural foramina that may result in a compression of lumbosacral nerve roots. Spinal stenosis can occur at one or multiple levels, and the narrowing may be asymmetric. It is important to recognize that 20% to 30% of asymptomatic adults older than 60 years have imaging evidence of spinal stenosis.[45] The prevalence of symptomatic lumbar spinal stenosis is not established. It is, however, the most frequent indication for spinal surgery in patients older than 65 years.

Congenital idiopathic spinal stenosis (Table 47-4) is not uncommon and results from congenitally short pedicles. These patients tend to become symptomatic early (in the third to fifth decade of life) when superimposed mild degenerative changes that would normally be tolerated result in sufficient further narrowing of the spinal canal to cause symptoms.[45]

Degenerative changes are the cause of spinal stenosis in the vast majority of cases. The intervertebral disk loses height while it degenerates. This results in a bulging or buckling of the now redundant and often hypertrophied ligamentum flavum into the posterior part of the canal. Any herniation of the degenerated disk narrows the anterior part of the canal, whereas hypertrophied facets and osteophytes may compress nerve roots in the lateral recess or intervertebral foramen (Figures 47-8 and 47-9). Any degree of spondylolisthesis will further exacerbate spinal canal narrowing.

The hallmark of spinal stenosis is neurogenic claudication (pseudoclaudication). The symptoms of neurogenic claudication are usually bilateral but often asymmetric. The patient's primary complaint is of pain in the buttocks, thighs, and legs. The buttock pain is sometimes described as a burning sensation. The pain may be accompanied by paresthesias. Neurogenic claudication is induced by standing erect or walking and relieved by sitting or flexing forward. This forward flexion increases the spinal canal dimensions, and may lead to the patient adopting a simian stance. It is therefore not surprising that these patients often feel relief by stooping forward while holding onto a shopping cart (the "shopping cart sign"), and may exhibit surprising endurance while pedaling a stationary bicycle. Symptoms of neurogenic claudication probably represent intermittent mechanical and ischemic disruption of lumbosacral nerve root function.[46] The patients also often have a sense of weakness in the lower extremities. Unsteadiness of gait, related to compression of proprioceptive fibers, is a frequent complaint. The finding of a wide-based gait in a patient with LBP has more than 90% specificity for lumbar spinal stenosis.[47] Intermittent priapism with walking has been described.[48] Factors that favor a diagnosis of neurogenic claudication versus vascular claudication include preservation of pedal pulses, provocation of symptoms by standing erect just as readily as by walking, relief of symptoms with flexion of the spine, and location of maximal discomfort in the thighs rather than the calves.

The physical examination of a patient with lumbar spinal stenosis is often unimpressive.[9] Severe neurologic deficits are uncommon. Lumbar range of motion may be normal or reduced, and the result of straight leg–raising is usually negative. An abnormal Romberg test is seen in some patients. Deep tendon reflexes and vibration sense may be reduced. Mild diffuse weakness in the lower extremities may be present in others. The significance of these findings is

often difficult to determine in elderly patients. However, in a few patients with spinal stenosis, a fixed nerve root injury may occur, resulting in a lumbosacral radiculopathy or, rarely, a cauda equina syndrome.

The diagnosis of lumbar spinal stenosis is most often suspected when a history of neurogenic claudication is elicited. The diagnosis is best confirmed by MRI.

Spinal stenosis is generally an indolent condition in which the symptoms evolve gradually and the natural history is benign. In a study of patients with lumbar spinal stenosis followed up for 49 months without surgical intervention, symptoms remained unchanged in 70%, improved in 15%, and worsened in 15%.[49] As such, prophylactic surgical intervention is not warranted.[45]

## DIFFUSE IDIOPATHIC SKELETAL HYPEROSTOSIS

Diffuse idiopathic skeletal hyperostosis (DISH) is characterized by calcification and ossification of paraspinous ligaments and the entheses.[50] It is a non-inflammatory condition of unknown etiology that is not associated with human leukocyte antigen (HLA)-B27 positivity.

DISH has been associated with obesity, diabetes mellitus, and acromegaly.[51] It is rarely diagnosed before 30 years, is more commonly seen in men, and the prevalence rises with age.[52]

The thoracic spine is most commonly involved, although the cervical and lumbar regions may also be affected. Ossification of the anterior longitudinal ligament is best seen on a lateral radiograph of the thoracic spine. The ossification, together with bridging enthesophytes in the spine, give the appearance of flowing wax on the anterior and right lateral aspects of the spine. Involvement of the left lateral aspect in patients with situs inversus has led to speculation that the descending aorta plays a role in the location of the calcification. Intervertebral disk spaces and facet joints are preserved (unless there is co-existing lumbar spondylosis) and the sacroiliac joints appear normal. This helps to differentiate DISH from spondylosis and the spondyloarthritides. Almost any extraspinal osseous or articular site may be affected.[53] Irregular new bone formation ("whiskering") is often best seen at the iliac crests, ischial tuberosities, and femoral trochanters. Ossification of tendons and ligaments at sites of attachment (such as the patella, olecranon process, and calcaneus) and periarticular osteophytes (such as the lateral acetabulum and inferior portion of the sacroiliac joint on pelvic radiographs) may also be seen. Severe ligamentous calcification may be seen in the sacrotuberous and iliolumbar ligaments and heterotopic bone formation following hip replacement in patients with DISH has been described.[54]

DISH may be entirely asymptomatic. The most common complaint encountered is of pain and stiffness involving the spine, often the thoracic region. Usually there is only a moderate limitation of spinal motion. Extensive ossification of the anterior longitudinal ligament, together with large anterior enthesophytes, may occasionally compress the esophagus and cause dysphagia.[50] Ossification of the posterior longitudinal ligament is almost exclusively seen in the cervical spine and may occur either as a discrete disorder or as part of DISH. This can rarely lead to cervical myelopathy. Pain and tenderness may be present at the entheses, and these patients may have findings of lateral or medial humeral epicondylitis, Achilles tendinitis, or plantar fasciitis.

If treatment of DISH is necessary at all, it is symptomatic. Most patients respond to acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), and judicious use of glucocorticoid injections for painful enthesopathy.

## Nonspecific Low Back Pain

This condition is also referred to as *idiopathic LBP.* As mentioned earlier, a precise pathoanatomic diagnosis, with identification of the pain generator, cannot be made in as many as 85% of the patients. This is largely because of the nonspecific nature of the symptoms in patients with LBP, and the weak association of these symptoms with findings on imaging. Thus terms such as lumbago, strain, and sprain have come into use. Strain and sprain have never been histologically characterized. Therefore nonspecific LBP is a more accurate label for these patients who have a mostly self-limited syndrome of acute mechanical LBP. The severity of pain can vary from mild to severe, and whereas sometimes the back pain develops immediately after a traumatic event such as lifting a heavy object or a twisting injury, other patients may simply wake up with LBP. Most patients are better within 1 to 4 weeks,[4] but remain susceptible to similar future episodes. Chronic nonspecific LBP develops in less than 10% of patients.

## Neoplasm

Neoplasms are an uncommon, but nevertheless important, cause of LBP. In a primary care setting, neoplasia accounts for less than 1% of cases of LBP.[14]

In a large prospective study of patients in a walk-in clinic, a history of cancer, unexplained weight loss, failure to improve after 1 month of conservative therapy, and age older than 50 years were each associated with a higher likelihood for cancer.[55] By far the most important predictor for the likelihood of underlying cancer as the cause of LBP was a prior history of cancer.

The typical patient with LBP secondary to spinal malignancy presents with a persistent and progressive pain that is not alleviated by rest and is often worse at night. In some patients a spinal mass can result in a lumbosacral radiculopathy or cauda equina syndrome. Acute LBP may be the presentation in a patient with a pathologic compression fracture. Rarely, leptomeningeal carcinomatosis (in patients with breast cancer, lung cancer, lymphoma, or leukemia) may present with a lumbosacral polyradiculopathy.[56]

Most cases result from involvement of the spine by metastatic carcinoma[5] (especially prostate, lung, breast, thyroid, or kidney) or multiple myeloma. Metastatic vertebral lesions, more commonly seen in the thoracic spine, account for 39% of bony metastases in patients with primary neoplasms.[57] Spinal cord tumors, primary vertebral tumors, and retroperitoneal tumors may in rare cases be the cause of LBP.[14]

Osteoid osteoma, a benign tumor of bone, typically presents with LBP in the second or third decade of life. The pain is often accompanied by a functional scoliosis secondary to paravertebral spasm. Patients may be seen with pain even before the osteoid osteoma is visible radiographically. Osteoid osteomas predominantly involve the posterior elements of the spine, usually the neural arch. A sclerotic lesion measuring less than 1.5 cm with a lucent nidus is pathognomonic.[58] A bone scan, CT scan, or MRI should be ordered if an osteoid osteoma is suspected but not detected on radiography. Symptoms can often be controlled by NSAIDs, presumably because the nidus produces high levels of prostaglandins. Surgical resection is an option for intolerable pain. Osteoid osteomas spontaneously resolve during the course of several years.[59]

Plain radiographs are less sensitive than other imaging tests in detecting neoplastic lesions because approximately 50% of trabecular bone must be lost before a lytic lesion is visible.[11] Metastatic lesions may be lytic (radiolucent), blastic (radiodense), or mixed. The majority of metastases are osteolytic. Vertebral bodies are primarily involved because of their rich blood supply associated with red marrow, and unlike infections, the disk space is usually spared. It should be noted that a purely lytic lesion such as multiple myeloma will not be detected by a bone scan. MRI offers the greatest sensitivity and specificity in the evaluation of spinal tumors and is generally the modality of choice.

Radiation therapy is usually helpful in controlling the pain related to skeletal metastases. Decompressive surgery is often required if the spinal mass results in a nerve root compression syndrome.

## Infection

Vertebral osteomyelitis (spinal osteomyelitis, spondylodiskitis) may be acute (usually pyogenic) or chronic (pyogenic, fungal, or granulomatous). Acute vertebral osteomyelitis evolves during a period of a few days or weeks and is the major focus of this discussion.

Vertebral osteomyelitis usually results from hematogenous seeding, direct inoculation at the time of spinal surgery, or contiguous spread from an infection in the adjacent soft tissue. The lumbar spine is the most common site of vertebral osteomyelitis, followed by the thoracic and cervical spine.[60] *Staphylococcus aureus* is the most common microorganism, followed by *Escherichia coli*. Coagulase-negative staphylococci and *Propionibacterium acnes* are almost always the cause of exogenous osteomyelitis after spinal surgery, particularly if internal fixation devices are used.[60]

A source of infection is detected in approximately half the cases, with endocarditis diagnosed in as many as a third of cases of vertebral osteomyelitis.[60] Other common sites for the primary focus of infection are the urinary tract, skin, soft tissue, a site of vascular access, bursitis, or septic arthritis.[61] Most patients with hematogenous pyogenic vertebral osteomyelitis have underlying medical disorders, such as diabetes, coronary artery disease, immunosuppressive disorders, malignancy, and renal failure.[60,61] Intravenous drug abuse is also a risk factor for vertebral osteomyelitis.

Vertebral osteomyelitis may be complicated by an epidural or paravertebral abscess. This may result in neurologic complication.

Back pain is the initial symptom in most patients. The pain tends to be persistent, present at rest, exacerbated by activity, and at times well localized. Point tenderness on percussion over the spine has sensitivity but not specificity for vertebral osteomyelitis. Fever is present in only approximately half of the patients,[60] in part because most patients

are using analgesic medications. Because most cases of vertebral osteomyelitis result from hematogenous seeding, the dominant manifestations initially may be of the primary infection. An epidural abscess may result in a radiculopathy or cauda equina syndrome.

Leukocytosis is seen in only approximately two-thirds of the patients. However, almost all the patients have increases in the erythrocyte sedimentation rate and C-reactive protein, with the latter best correlating with clinical response to therapy.[61] If blood cultures are negative in a patient suspected of having vertebral osteomyelitis, a bone biopsy (CT-guided or open) with appropriate culture studies and histopathologic analysis is indicated.

Plain radiography is usually the initial imaging study. Radiographic changes, however, occur relatively late and are nonspecific. Typically there is loss of disk height and loss of cortical definition followed by bony lysis of adjacent vertebral bodies. MRI is the most sensitive and specific imaging technique to detect spinal infections. The classic finding of pyogenic osteomyelitis is involvement of two vertebral bodies with their intervening disk.[11] In a patient with neurologic impairment, MRI should be done early to rule out an epidural abscess. Whenever possible, antimicrobial therapy should be directed against an identified susceptible pathogen. There are no data from randomized, controlled trials to guide decisions about specific antimicrobial regimens or the duration of therapy.[61] Intravenous therapy of at least 4 to 6 weeks, and possibly additional oral antibiotic therapy, is usually recommended. Surgery may be necessary to drain an abscess, although CT-guided catheter drainage may be sufficient in some cases. Surgical débridement is always required when infection is associated with a spinal implant with removal of the implant whenever possible.[61]

Tuberculosis and nontubercular granulomatous infections (blastomycosis, cryptococcosis, actinomycosis, coccidioidomycosis, and brucellosis) of the spine should be considered in the appropriate clinical and geographic setting.

Lumbar nerve roots are commonly involved in patients with herpes zoster. In most cases a single unilateral dermatome is involved. Pain is often severe and may precede the appearance of a maculopapular rash that evolves into vesicles and pustules.

Pyogenic sacroiliitis is rare. Patients, often children or young adults, present with back pain that may radiate into the buttock or posterior thighs. The sacroiliac joints are usually tender to palpation. MRI is the most sensitive imaging modality. Immediate CT-guided needle biopsy and culture, followed by appropriate antibiotic therapy, will usually produce an excellent outcome.[62]

## Inflammation

The spondyloarthritides cause inflammatory LBP (see Table 47-1) and are discussed in detail elsewhere (see Chapters 74 to 78).

## Metabolic Disease

The major consideration in this category is the occurrence of acute mechanical LBP secondary to a vertebral compression fracture in a patient with osteoporosis (see Chapter 101). Most patients are post-menopausal women.

Paget's disease of bone (see Chapter 101) is most often detected in an asymptomatic patient by the incidental finding of either an elevated alkaline phosphatase or characteristic radiographic abnormality. The spine is the second most commonly affected site after the pelvis. Within the spine, the L4 and L5 vertebrae are most commonly involved.[63] Paget's disease of the spine may involve single or multiple levels. The vertebral body is almost always involved together with a variable portion of the neural arch. Radiographically, Paget's disease is seen as areas of enlargement of the bone with thickened, coarsened trabeculae. Usually a mixed picture of sclerotic and lytic Paget's disease is encountered. The vertebrae may enlarge, weaken, and fracture. LBP may occur because of the pagetic process itself (with periosteal stretching and vascular engorgement), microfractures, overt fractures, secondary osteoarthritis of the facet joints, spondylolysis with or without spondylolisthesis, or sarcomatous transformation (rare).[63] Neurologic complications secondary to Paget's disease of the lumbar spine include sciatica secondary to nerve root impingement, spinal stenosis, and, rarely, cauda equina syndrome.

## Visceral Pathology

Disease in organs that share segmental innervation with the spine can cause pain to be referred to the spine. In general, pelvic diseases refer pain to the sacral area, lower abdominal diseases to the lumbar area, and upper abdominal diseases to the lower thoracic spine area. Local signs of disease, such as tenderness to palpation, paravertebral muscle spasm, and increased pain on spinal motion, are absent.

Vascular, gastrointestinal, urogenital, or retroperitoneal pathology may on occasion cause LBP. A partial list of causes includes an expanding aortic aneurysm, pyelonephritis, ureteral obstruction due to renal stones, chronic prostatitis, endometriosis, ovarian cysts, inflammatory bowel disorders, colonic neoplasms, and retroperitoneal hemorrhage (usually in a patient taking anti-coagulants).

Most abdominal aortic aneurysms are asymptomatic but may become painful as they expand. Aneurysmal pain is usually a harbinger of rupture. Rarely, the aneurysm may develop leakage. This produces severe pain with abdominal tenderness. Most patients with aortic dissection present with a sudden onset of severe "tearing" pain in the chest or upper back. Pain originating from a hollow viscus such as the ureter or colon is often colicky.

## Miscellaneous

LBP may be part of the clinical spectrum in innumerable conditions. It would not be practical or useful to discuss these entities here. Considered next are some of the more important or controversial causes of LBP.

The piriformis syndrome is thought to be an entrapment neuropathy of the sciatic nerve related to anatomic variations in the muscle-nerve relationship or to overuse. The piriformis is a narrow muscle that originates from the anterior part of the sacrum and inserts into the greater trochanter. It is an external rotator of the hip. There is, however, debate about the existence of the piriformis syndrome as a

discrete entity because of the lack of objective, validated, and standardized tests. The diagnosis is clinical. Patients complain of pain and paresthesias in the gluteal region that radiate down the leg to the foot. Unlike sciatica from lumbosacral nerve root compression, the pain is not restricted to a specific dermatome. The straight leg–raising test is usually negative. There may be tenderness over the sciatic notch. Physical examination maneuvers for the diagnosis of piriformis syndrome are based on the notion that stretching the irritated piriformis muscle may provoke sciatic nerve compression. This can be done by internally rotating the hip (Freiburg's sign) or by flexion, adduction, and internal rotation (FAIR maneuver) of the hip. Physical therapy that focuses on stretching the piriformis muscle and NSAIDs are generally the treatments offered. In refractory patients, local anesthetic, corticosteroid, and botulinum toxin injections have been used.

Sacroiliac joint dysfunction is a controversial diagnosis. It is a term used to describe pain in the sacroiliac region related to abnormal sacroiliac joint movement or alignment. However, tests of pelvic symmetry or sacroiliac joint movement have low intertester reliability, and fluoroscopically guided sacroiliac joint injections have been unreliable in diagnosis and treatment.[64,65] Radiographic degenerative changes of the sacroiliac joint are often noted in the evaluation of patients with LBP. Whether these changes are the primary cause of the back pain remains unresolved.[66]

Lumbosacral transitional vertebrae include sacralization of the lowest lumbar vertebral body (assimilation of L5 to the sacrum) and lumbarization of the uppermost sacral segment (assimilation of S1 to lumbar spine). These common variants can be seen in 15% to 35% of the general population.[67] The association of these variants with LBP remains controversial.

A "back mouse" is a mobile subcutaneous fibro-fatty nodule in the lumbosacral area. The nodule may be tender. Although there are case reports of patients with LBP and "back mice,"[68] the association with LBP remains unproven.

Epidural lipomatosis may be seen in obese patients, but it is more commonly seen as a rare side effect of long-term use of corticosteroids. There is an increase in epidural adipose tissue that causes a narrowing of the spinal canal. This is usually an incidental finding, although it may lead to compression of neural structures.

LBP during pregnancy is common. The pain usually starts between the fifth and seventh months of pregnancy.[69] The etiology of LBP in pregnancy is unclear. Biomechanical, hormonal, and vascular factors have been implicated. Most women have resolution of their pain postpartum.

Fibromyalgia (see Chapter 52) and polymyalgia rheumatica (see Chapter 88) are two frequently encountered rheumatologic conditions in which LBP may be a prominent part of the clinical syndrome.

## TREATMENT

Specific treatment is available only for the small fraction of patients with LBP who have either evidence of clinically significant neural compression or an underlying systemic disease (cancer, infection, visceral disease, and spondyloarthritis). In the vast majority of patients with LBP, either the precise pathoanatomic cause (i.e., the pain generator) cannot be determined or, when the cause is determined, no specific treatment is available. These patients are managed with a conservative program centered on analgesia, education, and physical therapy. The goal of treatment is relief of pain and restoration of function. Surgery is rarely necessary (Figure 47-10).

One should be wary of the proliferation of unproven medical, surgical, and alternative therapies. Most have not been rigorously tested in well-designed randomized controlled trials. Uncontrolled studies can produce a misleading impression of efficacy because of fluctuating symptoms and the largely favorable natural history of LBP in most patients.

For management purposes, patients with LBP are considered to have either acute LBP (duration <3 months), chronic LBP (duration >3 months), or a nerve root compression syndrome.

### Acute Low Back Pain

The typical patient seeks medical attention for sudden onset of severe mechanical LBP. Examination usually reveals paravertebral muscle spasm, which often results in loss of the normally present lumbar lordosis and a severe decrease in range of motion secondary to pain. The prognosis for acute LBP is excellent. Indeed, only approximately a third of these patients seek medical care and more than 90% recover within 8 weeks or less.[70]

Patients with acute LBP are advised to stay active and continue ordinary daily activities within the limits permitted by pain. This leads to more rapid recovery than bed rest.[71] Bed rest of more than 1 or 2 days is discouraged.

Pharmacologic therapy is used for symptomatic relief and does not affect recovery time. Unfortunately, no medication has consistently been shown to result in large average benefits on pain, and evidence of beneficial effects on function is even more limited.[8] In spite of limited efficacy,[72] acetaminophen and NSAIDs are first-line options for analgesia. Short-term use of opioids is reasonable in patients with severe disabling LBP or in those at high risk of complications because of NSAIDs. For patients with acute LBP, short-acting opioids are generally recommended. Muscle relaxants are moderately effective for short-term symptomatic relief but have a high prevalence of adverse effects, including drowsiness and dizziness.[8] It is unclear whether these medications truly relax muscles or if their effects are related to sedation or other nonspecific effects. Benzodiazepines have similar efficacy to muscle relaxants for short-term pain relief but are associated with risks for abuse, addiction, and tolerance.[24]

Back exercises are not helpful in the acute phase, and a physical therapy referral is usually unnecessary in the first month. Later, an individually tailored program that focuses on core strengthening, stretching exercises, aerobic conditioning, functional restoration, loss of excess weight, and education is recommended to prevent recurrences.[9,14] The purpose of back exercises is to stabilize the spine by strengthening trunk muscles. Flexion exercises strengthen the abdominal muscles, and extension exercises strengthen the paraspinal muscles. Numerous exercise programs have been developed and appear to be equally effective.

Patient education, including the use of education booklets, is strongly recommended.[24] The information provided

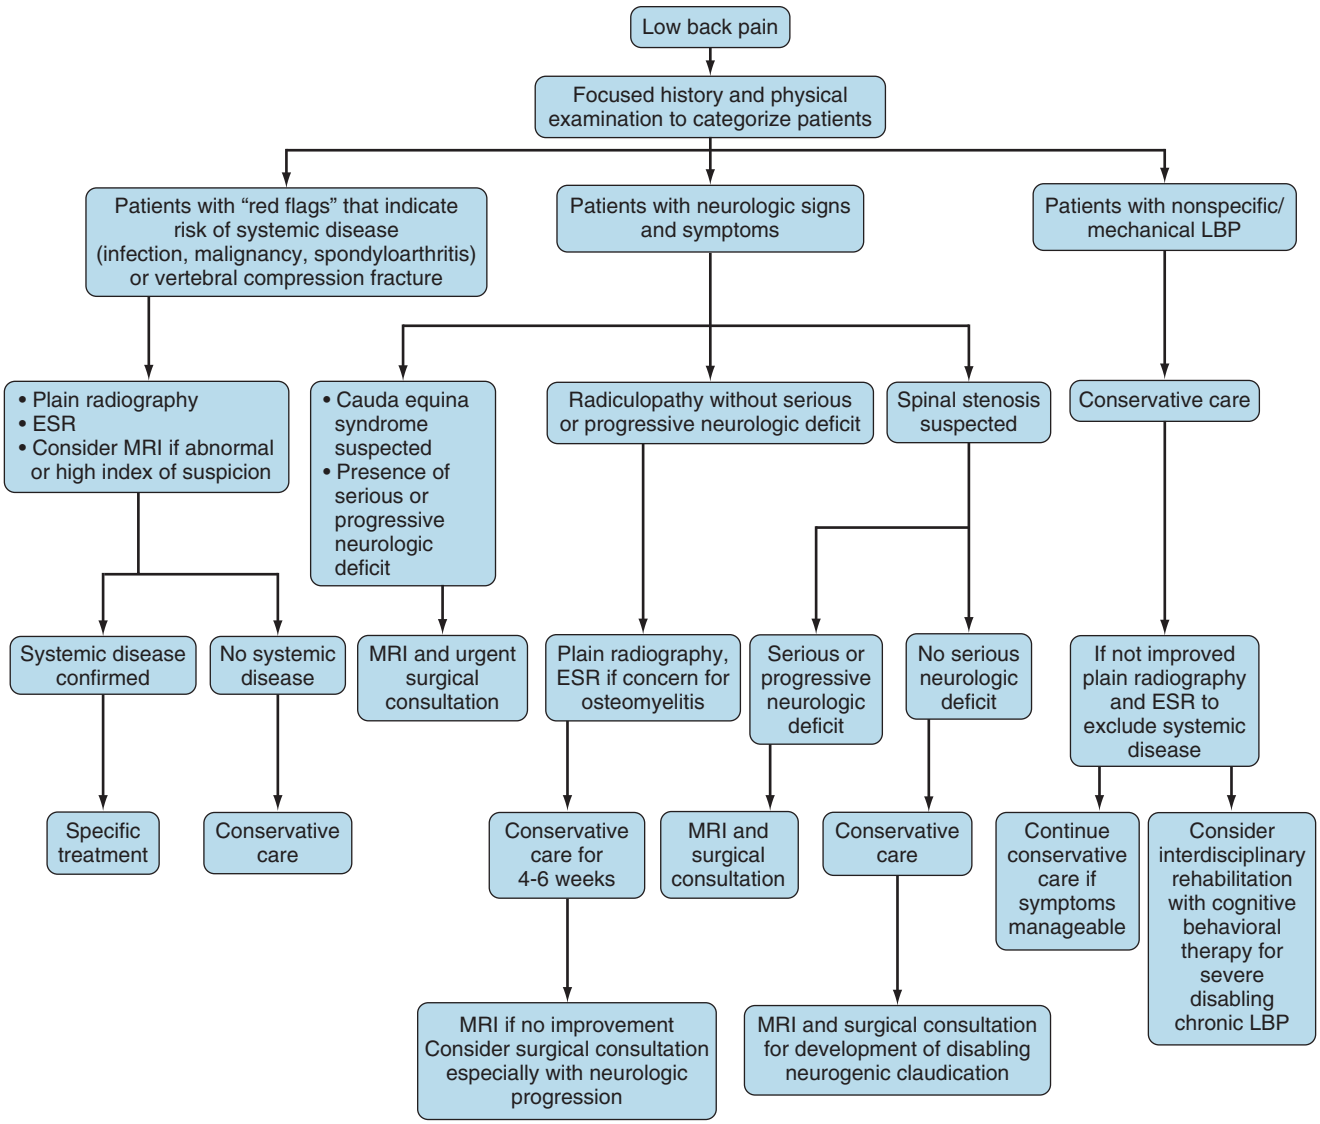

**Figure 47-10** Algorithm for the differential diagnosis and treatment of low back pain. ESR, Erythrocyte sedimentation rate; LBP, low back pain; MRI, magnetic resonance imaging.

should include causes of LBP, basic anatomy, favorable natural history, minimal value of diagnostic testing, importance of remaining active, effective self-care options, and coping techniques.

Spinal manipulation is provided mainly by chiropractors and osteopaths. It may involve low-velocity mobilization or manipulation with a high-velocity thrust that stretches spinal structures beyond the normal range and is frequently accompanied by a cracking or popping sound. For acute LBP, current evidence suggests that manipulative therapy is no more effective than conventional medical therapy.[24] There is no evidence that ongoing manipulation reduces the risk of recurrence of LBP.[73] There is insufficient evidence regarding the efficacy of massage and acupuncture in the treatment of acute LBP.[24]

Application of heat by heating pads or blankets is a reasonable self-care option for short-term relief of acute LBP. However, insufficient evidence exists to recommend application of cold packs or the use of corsets and braces.[24] Traction provides no significant benefit for LBP patients with or without sciatica.[74]

Injection therapy is used mostly in subacute (>6 weeks) and chronic LBP. Epidural corticosteroid injections have gained remarkable, but unjustified, popularity. The rationale for their use is that the genesis of radicular pain, when a herniated disk impinges on a nerve root, is at least partly related to locally induced inflammation. There is evidence of a small treatment benefit compared with placebo injection for short-term relief of leg pain in patients with radiculopathy resulting from a herniated nucleus pulposus.[75,76] However, epidural corticosteroid injections offer no significant functional benefit, nor do they reduce the need for surgery. It is important to note that there is no convincing evidence for the effectiveness of epidural corticosteroid injections in LBP patients without radiculopathy, in patients with spinal stenosis and neurogenic claudication,[77] or for

failed back surgery syndrome. Nonetheless, most of the use of epidural steroid injections occurs in these situations of questionable benefit.[78] The U.S. Food and Drug Administration (FDA) has not approved the use of epidural corticosteroid injections. In April 2014 the FDA issued a drug safety communication requiring label changes to warn of rare but serious neurologic problems (including loss of vision, stroke, and death) after epidural corticosteroid injections. This safety issue is unrelated to the contamination of compounded corticosteroid injections products used for epidural injections that was reported in 2012.

A variety of other injection therapies with glucocorticoids or anesthetic agents, often in combination, are used in individuals with LBP with or without radicular pain and other symptoms in the leg. These include injection of trigger points, ligaments, sacroiliac joints, facet joints, and intradiskal steroid injections. There is no convincing evidence of the efficacy of these interventions.[79,80] Medial branch block for presumed facet joint pain and nerve root blocks for therapeutic or diagnostic purposes are also not recommended.[80] Unfortunately, these invasive and expensive procedures are commonly used in interventional pain clinics.

A number of physical therapy modalities are currently used in the treatment of patients with subacute and chronic LBP. These include transcutaneous electrical nerve stimulation (TENS), percutaneous electrical nerve stimulation, interferential therapy, low-level laser therapy, shortwave diathermy, and ultrasound. There is insufficient evidence of efficacy to recommend their use.

Vertebral compression fractures secondary to osteoporosis are common. There is resolution of pain with fracture healing within a few weeks in most patients. Vertebroplasty and balloon kyphoplasty are two increasingly popular, invasive, and expensive procedures that are used to treat persistent pain associated with these fractures. Both procedures involve the percutaneous placement of needles into the vertebral body through or lateral to the pedicles, as well as the injection of bone cement to stabilize the fracture. Kyphoplasty differs from vertebroplasty in that the cement is injected into a void in the vertebral body created by inflation of a balloon. Several early studies had suggested a positive treatment effect for vertebroplasty.[81] However, two blinded, randomized, placebo-controlled trials of vertebroplasty for painful osteoporotic spinal fractures found no beneficial effect of vertebroplasty compared with a sham procedure.[82,83] A subset analysis of data from these trials confirmed that the lack of benefit from vertebroplasty extended to patients with pain of recent onset (<6 weeks) and to those with severe pain.[84] Therefore, on the basis of current evidence, the routine use of vertebroplasty or indeed kyphoplasty for relief of pain from osteoporotic compression fractures cannot be justified.[85]

## Chronic Low Back Pain

The clinical spectrum in patients with chronic LBP is wide. Some complain of severe, unrelenting pain, but most have a nagging mechanical LBP that may radiate into the buttocks and upper thighs. Patients with chronic LBP may experience periods of acute exacerbation. These exacerbations are managed according to the principles discussed earlier. A significant number of patients with chronic LBP remain functional and continue working, but overall, the results of treatment are unsatisfactory, and complete relief of pain is unrealistic for most. There is evidence that in a subset of patients with chronic LBP a pattern of augmented central nervous system (CNS) pain processing (similar to fibromyalgia) is present suggesting a component of "centralized pain."[86] These patients are more likely to have poor treatment outcomes. Patients with chronic LBP are largely responsible for the high costs associated with LBP. It is therefore incumbent on physicians who treat these patients to judiciously use proven therapies.

For most patients, first-line medication options are acetaminophen or NSAIDs. They may provide some degree of analgesia, but the evidence for their long-term efficacy is not compelling. Opioid analgesics or tramadol are an option when used judiciously in patients with severe disabling pain. Because of substantial risks, including aberrant drug-related behaviors with long-term use in patients vulnerable to abuse or addiction, potential benefits and harms of opioid analgesics should be carefully weighed before starting therapy.[24,87] The co-prescribing of opioids and benzodiazepines should be avoided. There is no evidence that long-acting, around-the-clock dosing is more effective than short-acting or as-needed dosing, and continuous exposure to opioids could induce tolerance and lead to dose escalations.[8] Muscle relaxants are not recommended for long-term use in patients with chronic stable LBP. Anti-depressants that inhibit norepinephrine uptake are thought to have pain-modulating properties independent of their effects on depression. As such, low-dose tricyclic anti-depressants are an option for chronic LBP, although the treatment effect is small and adverse side effects are common.[8] There is no evidence of efficacy of selective serotonin reuptake inhibitors for LBP. Depression is, however, common in patients with chronic LBP and should be treated appropriately. Duloxetine, a serotonin-norepinephrine reuptake inhibitor, may have marginal efficacy in patients with chronic LBP.[88,89] There is insufficient evidence to recommend antiepileptic medications, such as gabapentin and topiramate, for pain relief in patients with LBP with or without radiculopathy.[8]

An individually tailored physical therapy program and patient education, as discussed in the earlier section on the treatment of acute LBP, are particularly important aspects in the management of a patient with chronic LBP. The use of physical therapy modalities and injection techniques (as discussed earlier) is not recommended for patients with chronic LBP. Lumbar supports and traction are ineffective. For most patients with LBP a medium-firm mattress or a back-conforming mattress (waterbed or foam) may be superior to a firm mattress.[90,91]

A number of physical treatments have been used to treat chronic LBP. Spinal manipulation has been shown to be superior to sham manipulation, but it is no more effective than conservative medical therapy.[92] A recent meta-analysis suggested that osteopathic manipulative treatment improves pain and functional status in acute and chronic nonspecific LBP. However, the studies included had small sample sizes, different comparison groups in different studies, and lack of long-term measurement.[93] There is less evidence for the efficacy of massage and acupuncture.[92] Trial data, including randomized studies,[94,95] suggest that a yoga program can be effective in reducing pain and improving function in some

patients with chronic or recurrent LBP, with benefits lasting at least several months.

There has been a proliferation of nonsurgical interventional therapies for back pain. Various injection therapies (such as injections of trigger points, facet joints, and nerve root blocks) as discussed under the treatment of acute LBP, lack convincing evidence of efficacy and as such are not recommended in the treatment of patients with chronic LBP.

Radiofrequency denervation has most commonly been used for the treatment of presumed facet joint pain by targeting the medial branch of the primary dorsal ramus. It involves fluoroscopic placement of an electrode near the nerve and application of heat by using a radiofrequency current to coagulate the nerve. There is a lack of convincing evidence about the effectiveness of this invasive procedure.[79] Intradiskal electrothermal therapy (IDET) and percutaneous intradiskal radiofrequency thermocoagulation (PIRFT) involve placement of an electrode into the intervertebral disk of patients with presumed diskogenic pain and using electric or radiofrequency current to provide heat to thermocoagulate and shrink intradiskal tissue and destroy nerves. Current evidence does not support the use of IDET or PIRFT.[79,96] Prolotherapy (also referred to as *sclerotherapy*) involves repeated injections of an irritant sclerosing agent into ligaments and tendinous attachments. It is based on the hypothesis that back pain in some patients stems from weakened ligaments and repeated injections of a sclerosing agent will strengthen the ligaments and reduce pain. On the basis of trial data, a guideline from the American Pain Society recommends against prolotherapy for chronic LBP.[79]

Spinal cord stimulation is a procedure involving the placement of electrodes, percutaneously or by laminotomy, in the epidural space adjacent to the area of the spine presumed to be the source of pain and applying an electric current in order to achieve sympatholytic and other neuromodulatory effects.[79] Power for the spinal cord stimulator is supplied by an implanted battery. Spinal cord stimulation is associated with a greater likelihood for pain relief compared with reoperation or conventional medical management in patients with failed back surgery syndrome with persistent radiculopathy.[79] At present there is no good evidence for the use of spinal cord stimulation for chronic LBP not related to the failed back surgery or failed back surgery syndrome without radiculopathy. Approximately a third of the patients involved in studies have experienced a complication following spinal cord stimulation implantation, including electrode migration, infection, wound breakdown, and lead- and generator pocket–related complications.[79]

Intraspinal drug infusion systems, with use of a subcutaneously implanted pump with attached catheter, have been used in some patients with chronic intractable LBP for the intrathecal delivery of analgesics, usually morphine. Adequate evidence to support this intervention is not available.

Chronic LBP is a complex condition that involves biologic, psychological, and environmental factors. For patients with persistent and disabling nonradicular LBP despite recommended noninterdisciplinary therapies, the clinician should strongly consider intensive interdisciplinary rehabilitation with an emphasis on cognitive-behavioral therapy.[80] Interdisciplinary rehabilitation (also called *multidisciplinary therapy*) is an intervention that combines and coordinates physical, vocational, and behavioral components and is provided by multiple health professionals with different clinical backgrounds. Cognitive-behavioral therapy is a psychotherapeutic intervention that involves working with cognitions to change emotions, thoughts, and behaviors. There is strong evidence of improved function and moderate evidence of pain improvement with intensive interdisciplinary rehabilitation programs.[29] Functional restoration (also called *work hardening*) is an intervention that involves simulated or actual work in a supervised environment to enhance job performance skills and improve strength, endurance, flexibility, and cardiovascular fitness in injured workers. When combined with a cognitive-behavioral component, functional restoration is more effective than standard care alone to reduce time lost from work.[92]

As previously discussed, the precise identification of the pain generator in an LBP patient with degenerative changes involving the lumbar spine and no radicular pain is usually not possible in contradistinction to the patient with radicular symptoms. It is therefore not surprising that, as a general rule, the results of back surgery are disappointing when the goal is relief of back pain rather than relief of radicular symptoms resulting from neurologic compression. As such, the role of surgical treatment for chronic disabling LBP without neurologic involvement in patients with degenerative disease remains controversial. The most common surgery performed is spinal fusion. In spite of the unclear efficacy, rates of spinal fusion surgery for this indication are rapidly increasing. Interbody fusion is achieved from either a posterior or an anterior approach or both combined for a circumferential fusion. All fusion techniques involve placement of a bone graft between the vertebrae. Instrumentation refers to the use of hardware, such as screws, plates, or cages, that serve as an internal splint while the bone graft heals. Bone morphogenetic proteins are sometimes used to speed fusion. The rationale for fusion is based on its successful use at painful peripheral joints.

The current evidence is that for nonradicular back pain with degenerative changes, fusion is no more effective than intensive interdisciplinary rehabilitation but is associated with small to moderate benefits compared with standard nonsurgical care.[97] Furthermore, the majority of patients who undergo surgery do not experience an optimal outcome defined as no pain, discontinuation or occasional pain medication use, and return of high-level function.[80]

Lumbar disk replacement with a prosthetic disk is a newer alternative to fusion. Disk replacement is approved in the United States for patients with disease limited to one disk between L3-S1 and no spondylolisthesis or neurologic deficit. Approval was based on data showing efficacy equal to that of spinal fusion. This may be faint praise, given the controversy regarding the efficacy of spinal fusion for lumbar disk disease. No data support the hypothetical advantage that, unlike spinal fusion, prosthetic disks will protect adjacent levels from further degeneration by preserving motion. At present there is insufficient evidence regarding the long-term benefits and risk of disk replacement to support its recommendation.

Most patients with LBP, including those with neurogenic signs and symptoms, do not require surgical treatment.

## Spine Patient Outcomes Research Trial

The precise role of surgery in the care of patients with LBP and neurogenic signs and symptoms is often unclear and controversial. This prompted the National Institute of Arthritis and Musculoskeletal and Skin Diseases (NIAMS) to fund three large parallel randomized[98-101] Spine Patient Outcomes Research Trial (SPORT) studies in an effort to assess the role of surgery in patients with lumbar disk herniation, lumbar degenerative spondylolisthesis with spinal stenosis, or lumbar spinal stenosis. Of note, in each of these milestone studies, all the patients had radicular leg pain with associated neurologic signs or neurogenic claudication. Patients with serious or progressive neurologic deficits require urgent surgical decompression and, as such, were excluded from all the SPORT studies. Each study included a randomly assigned cohort and an observational cohort. Patients in the observational cohort declined to be randomly assigned in favor of designating their own treatment, but agreed to undergo follow-up according to the same protocol. The primary study outcomes were measures of pain, physical function, and disability during a 2-year period. All three studies were compromised by high rates of crossover (as much as 50%) between the assigned treatment, surgical or nonsurgical, in both cohorts. This has caused concern over the validity of the conclusions.

The first study[98,99] looked at surgical (discektomy) versus nonoperative treatment (physical therapy, education, NSAIDs if tolerated) in patients with persistent symptoms despite nonoperative treatment for at least 6 weeks. Both treatment groups improved substantially; the intent-to-treat analysis showed no significant difference in the randomly assigned cohort.[98] Greater improvement with surgery was reported in the observational cohort.[99] However, nonrandomly assigned comparisons of self-reported outcomes are subject to potential confounding and must be interpreted cautiously.

In the second study, in patients with lumbar degenerative spondylolisthesis and spinal stenosis, with persistent symptoms for at least 12 weeks, the intent-to-treat analyses for the randomly assigned cohort showed no significant differences between the surgical (decompressive laminectory with or without fusion) and usual nonsurgical treatment. The nonrandomly assigned "as treated" comparison that combined both cohorts showed greater improvement in the surgical group. "As treated" analyses are significantly confounded and should be interpreted with caution.[102]

In the final study[101] for patients with lumbar spinal stenosis without spondylolisthesis, with persistent symptoms for at least 12 weeks, both the intent-to-treat and "as treated" analyses showed a significant advantage favoring surgery (posterior decompressive laminectomy).

SPORT data also revealed that, in general, spinal surgery improves leg pain more than LBP, and people with diabetes tend to experience less relief from spinal surgery.[103,104]

## Disk Herniation

Patients with a herniated disk with radicular pain secondary to nerve root compression should be treated nonsurgically, as described in the section on acute LBP unless they have a serious or progressive neurologic deficit. Only approximately 10% of patients have sufficient pain after 6 weeks of conservative care that surgery is considered.[14] A decision to continue with nonsurgical therapy beyond 6 weeks in these patients does not increase the risk for paralysis or cauda equina syndrome.[80] Surgery in these patients is associated with moderate short-term (through 6 to 12 weeks) benefits compared with nonsurgical therapy, although differences in outcome diminish with time and are generally no longer present after 1 to 2 years.[74,80]

Open diskectomy or microdiskectomy is the usual surgery performed on patients with serious or progressive neurologic deficit or electively on patients with persistent disabling pain secondary to radiculopathy (Table 47-5). Open diskectomy generally involves a laminectomy, whereas microdiskectomy, by using a smaller incision and an operating microscope, involves a hemilaminectomy to remove the disk fragment compressing the nerve root. There are no clear differences in the outcome between open diskectomy and microdiskectomy. There is insufficient evidence to evaluate the efficacy of sequestrectomy, or various laser-assisted, endoscopic, percutaneous, and other minimally invasive methods.[97,105]

Epidural corticosteroid injections may offer a small treatment benefit for short-term relief of radicular pain but do not offer significant functional benefit and do not reduce the need for surgery.[75]

Anti–tumor necrosis factor (TNF) therapy is under investigation in patients with lumbar radiculopathy.

There is biologic plausibility for its potential efficacy in sciatica because TNF is an important mediator of nerve root inflammation, central sensitization, and neuropathic pain.[106] However, there have been conflicting results in small randomized control trials looking at patients with radiculopathy. The addition of a short course of subcutaneous adalimumab to the treatment regimen of patients with acute sciatica resulted in a small decrease in leg pain and fewer surgical procedures.[107] However, another trial found no difference between intravenous infliximab and a saline infusion.[108] In a three-group trial, leg pain appeared to be reduced more with epidural steroids than with epidural etanercept or saline.[109] The results of the etanercept group were no better than the saline group. Yet a trial that used the transforaminal approach to deliver epidural etanercept concluded that etanercept reduced both leg and back pain compared with placebo.[106]

| Serious or progressive neurologic deficit |

### Spinal Stenosis

It is critical to understand the natural history of degenerative lumbar spinal stenosis before making treatment decisions. The symptoms of spinal stenosis remain stable for years in most patients and may improve in some. Dramatic improvement is uncommon. Even when symptoms progress, there is little likelihood of rapid deterioration of neurologic function. Therefore conservative nonoperative treatment is a rational choice for most patients.

There is a paucity of good data to guide the conservative management of lumbar spinal stenosis. Physical therapy is the mainstay of management, but evidence for the efficacy of specific standardized regimens is not available. Most regimens include core strengthening, stretching, aerobic conditioning, loss of excess weight, and patient education. Exercises that involve lumbar flexion, such as bicycling, are better tolerated. Strengthening of abdominal muscles may be helpful by promoting lumbar flexion and reducing lumbar lordosis. Lumbar corsets that maintain slight flexion may provide symptomatic relief. They should only be used for a limited number of hours a day to avoid atrophy of paraspinal muscles.

Acetaminophen, NSAIDs, and mild narcotic analgesics are used for symptomatic relief of pain.

Lumbar epidural corticosteroid injections are used on the assumption that symptoms may result from inflammation at the interface between the nerve root and compressing tissues.[45] To assess this potential for efficacy, a double-blind placebo controlled, randomized trial[77] was carried out in patients with lumbar spinal stenosis and associated moderate to severe leg pain. There was no significant difference between patients assigned to epidural injections of glucocorticoids plus lidocaine and those assigned to lidocaine alone with regards to the co-primary outcomes of functional disability or pain intensity. Based on this well-designed study, the routine use of epidural corticosteroids in patients with lumbar spinal stenosis cannot be recommended.

Surgery is indicated for the few patients with lumbar spinal stenosis who have a serious or progressive neurologic deficit. However, most surgery for lumbar spinal stenosis is elective. The indication for elective surgery is to relieve persistent and disabling symptoms of neurogenic claudication that have not responded to conservative care. In patients without fixed neurologic deficits, delayed surgery produces similar benefits to surgery selected as the initial treatment.[45,110] The surgical goal is to decompress the central spinal canal and the neural foramina to eliminate pressure on the nerve roots. This is accomplished by laminectomy, partial facetectomy of hypertrophied facet joints, and excision of the hypertrophied ligamentum flavum and any protruding disk material. Laminectomy with lumbar fusion should generally be reserved for patients who have spinal stenosis with spondylolisthesis. Unfortunately, there is an alarming increase in spinal fusion surgery with routine use of complex fusion techniques in the absence of evidence of greater efficacy. The techniques include instrumentation, bone graft augmentation with bone cement and human bone morphogenetic proteins, and combined anterior and posterior fusion (often at multiple levels). These techniques are associated with increased perioperative mortality, major complications, rehospitalization, and cost in the absence of evidence of greater efficacy.[111-113]

Overall, for patients with spinal stenosis, with or without spondylolisthesis, who have disabling symptoms of neurogenic claudication despite conservative care, there is some evidence to support the effectiveness of decompressive laminectomy in reducing pain and improving function through 1 to 2 years.[45,80,97,101] Beyond this time frame, the benefits appear to diminish.

A less invasive alternative to decompressive laminectomy is the implantation of a titanium interspinous spacer at one or two vertebral levels. This spacer distracts adjacent spinous processes and thereby imposes lumbar flexion, which in turn potentially increases the spinal canal dimensions. There is preliminary evidence of efficacy in patients with one- or two-level spinal stenosis, without spondylolisthesis, and with a history of relief of neurogenic claudication with flexion.[97] There are no trials comparing the interspinous spacer with decompressive surgery.

### Spondylolisthesis

The vast majority of patients with spondylolisthesis and chronic LBP are treated conservatively. Rarely, a patient may need decompression surgery with fusion if a serious or progressive neurologic deficit develops from nerve root impingement or disabling pseudoclaudication secondary to spinal stenosis develops in the patient. A randomized trial involving patients with isthmic spondylolisthesis and disabling isolated LBP or sciatica for at least a year suggested fusion surgery produced better results than nonsurgical care,[114] although the differences in outcome narrowed during a 5-year follow-up period.[115]

## OUTCOME

The natural history of most patients with acute LBP is favorable. There is substantial improvement in pain and function within a month in the majority of patients,[4] and more than 90% are better at 8 weeks.[5] Only approximately a third of patients with acute LBP seek medical care. Presumably, the rest improve on their own. Relapses, that also tend to be brief, are common and may affect as many as 40% of patients within 6 months.

Improvement is also the norm for patients with sciatica secondary to a herniated disk.[116] A third of these patients are significantly better in 2 weeks, and 75% improve after 3 months.[11] Only approximately 10% of these patients ultimately undergo surgery.

The symptoms of spinal stenosis tend to remain stable in 70% of patients, improve in 15%, and worsen in 15%.[49]

The 7% to 10% of patients in whom chronic pain develops are largely responsible for the high costs associated with LBP and remain a major challenge. Factors that predict persistence of chronic disabling LBP include maladaptive pain coping behaviors, presence of nonorganic signs, functional impairment, poor general health status, psychiatric comorbidities, job dissatisfaction, disputed compensation claims, and a high level of "fear avoidance" (an exaggerated fear of pain leading to avoidance of beneficial activities).[29,117]

## CONCLUSION

Of the general population, 80% will experience LBP. Of these patients, 90% will be largely pain free within 8 weeks. Degenerative change in the lumbar spine is the most commonly identified cause of LBP. The initial evaluation of LBP should focus on identifying the few patients with significant neurologic involvement, fracture, or systemic disease (infection, malignancy, or spondyloarthritis) because they may need urgent or specific intervention. Early imaging is rarely indicated in the absence of trauma, significant neurologic involvement, or suspicion of systemic disease. Imaging abnormalities, often the result of age-related degenerative changes, should be carefully interpreted because they are frequently present in asymptomatic individuals. A precise pathoanatomic diagnosis with identification of the pain generator cannot be made in 85% of patients. Regardless, most patients with the largely self-limited syndrome of acute LBP will only require reassurance, education, and simple analgesics. The management of patients with chronic LBP remains a challenge and complete relief of pain is an unrealistic goal for most. Patients with chronic LBP benefit from an initial program of core strengthening, stretching, aerobic conditioning, loss of excess weight, and education. Intensive interdisciplinary rehabilitation with an emphasis on cognitive-behavioral therapy should be strongly considered if conservative measures fail. Epidural corticosteroids have a small treatment benefit, and their use should be restricted to patients with radiculopathy because of disk herniation. A large number of injection techniques, physical therapy modalities, and nonsurgical interventional therapies lack evidence of efficacy. Decompressive surgery is indicated for serious or progressive neurologic deficit and is rarely needed.

Rates of back surgery (including spinal fusion) in the United States are the highest in the world and continue to rise rapidly.[97] This increase continues in spite of the fact that the role of surgery in the management of patients without serious or progressive neurologic deficit remains controversial. Randomized trials incorporating a sham operation may be the only way to resolve the controversy. Such trials may be justifiable because genuine clinical equipoise exists among clinicians about the merits of the intervention, the surgery is often not performed for a life-threatening condition, the primary outcomes are subjective, and the rate of complications is high.[102,113]

There continues to be a proliferation and increasing utilization of expensive but unproven interventional and alternative therapies. Whenever possible, these need to be subjected to randomized, placebo-controlled trials. This is the only truly valid means to assess the efficacy of interventions for subjective outcomes such as pain. Once the efficacy has been established, these treatments should be further subjected to "comparative effectiveness research" to determine how these effective interventions compare with each other.[118]

A promising new approach for the management of LBP in primary care involves stratified care according to the estimated risk of poor prognosis by using a validated and simple screening method, Patients are allocated into three different risk-defined groups (low, medium, and high) and treated according to three treatment pathways matched to the risk groups. This resulted in better clinical and economic outcomes than did nonstratified conventional care.[119] This strategy should be further explored and confirmed in different settings.

Evidence-based clinical practice guidelines regarding indications for tests or treatment at specific steps in the care of patients with LBP exist in many countries. They are intended to provide a cost-effective road map for rational and efficient care. The implementation of these guidelines, however, remains a challenge. Avenues that will facilitate this implementation should be explored.

CHAPTER 48

# Hip and Knee Pain

James I. Huddleston III • Stuart Goodman

**KEY POINTS**

- The clinician should be able to narrow the differential diagnosis down to two to three diagnoses after the history and physical examination.
- Imaging studies should be used to confirm the diagnosis.
- The initial imaging study ordered should be conventional radiographs.
- Many of the vital structures in the knee can be palpated easily or examined with provocative tests.
- A knee effusion is often associated with internal derangement.
- The clinician should suspect a torn meniscus if a patient has an effusion, joint line tenderness, and pain with hyperextension and hyperflexion.
- Patients with osteoarthritis often report stiffness and pain with activity.
- Inflammatory arthritis should be considered when a patient continues to experience pain despite resting the joint.
- Groin pain with internal rotation of the hip is considered to be due to hip disease until proven otherwise.
- Concurrent hip and lumbosacral disease is common.

Musculoskeletal pain affects one-third to one-half of the general population.[1,2] A substantial increase in the burden of musculoskeletal disease is expected in the next decade as the "Baby Boomers" reach middle age and beyond. This increased burden is exemplified by the increasing prevalence of hip and knee replacement operations, which rose by 16.2% to 884,400 procedures annually in the United States between 2002 and 2004.[3] Furthermore, the prevalence of total knee and total hip arthroplasty procedures is expected to double by 2016 and 2026, respectively.[4] The hip and knee joints are two of the most commonly affected sites of musculoskeletal pain, with the prevalence of hip pain ranging from 8% to 30% in people 60 years and older[5,6] and the prevalence of knee pain ranging from 20% to 52% in individuals 55 years and older. In general, women experience more musculoskeletal pain than do men.[7] Geographic and ethnic variations in the rates of both hip and knee pain also exist. For example, there tends to be significantly less hip and knee pain with decreasing latitude, as well as significantly less hip pain and osteoarthritis in China than in the United States.[8-15]

When evaluating reports of knee or hip pain, knowledge of the anatomy of these joints is necessary to formulate a differential diagnosis. Given the thin soft tissue envelope around the knee and the fact that knee pain is rarely referred, the pain generators around the knee often can be elucidated with a complete history and thorough physical examination. Diagnosis of hip pain may be more challenging because the joint is deeper and the region is not infrequently the site of referred pain from the spine. An understanding of the basic biomechanics of these joints is also important in formulating a differential diagnosis because certain activities are likely to cause specific injuries.

This chapter will focus on the important aspects of the history, physical examination, and imaging modalities involved in evaluating patients with reports of knee and hip pain. An appropriate, thorough workup of these patients will allow the clinician to formulate an accurate differential diagnosis in an efficient manner.

## KNEE PAIN

### History

A detailed history is perhaps the most important step in accurately diagnosing the cause of knee pain. Knee complaints generally fall into two broad categories: pain or instability. Pain may arise from injury to the articular surfaces (e.g., osteoarthritis, inflammatory arthritis, osteochondral defects, and osteochondritis desiccans), torn menisci, quadriceps and patella tendon tears, bursitis, nerve damage, fractures, neoplasia, or infection. Referred pain from the hip or spine is less common. Instability is usually episodic and stems from injuries to the quadriceps-patellar extensor mechanism, collateral ligaments, or cruciate ligaments. It is important to distinguish true instability from the common complaint of "giving way" because the latter is usually due to a robust pain response rather than specific structural disease.

People in certain age groups tend to experience similar injuries. Ligament injuries, acute meniscus tears, and patellofemoral problems are frequently encountered in patients younger than 40 years. In contrast, degenerative conditions such as osteoarthritis and degenerative meniscal lesions tend to occur more frequently in older people.

The location and character of the pain are particularly important when evaluating knee pain because many of the structures vital to proper knee function are subcutaneous and can be palpated easily. We prefer to conceptualize the knee as three separate compartments—medial, lateral, and patellofemoral. Each compartment should be examined separately. The patient should be able to point to the exact

area where the pain is most severe. The time of onset of the pain should be determined. Osteoarthritis and inflammatory arthritis tend to have an insidious onset, whereas injuries to menisci and ligaments are usually associated with a traumatic event. Knowing the details of a traumatic event will be helpful. For example, a twisting injury, especially one sustained with a flexed knee, suggests a meniscus tear, whereas a noncontact knee injury associated with change of direction is more likely to produce a tear of the anterior cruciate ligament (ACL). Pain from degenerative arthritis tends to be associated with stiffness, is generally worse with ongoing activity during the day, and is exacerbated by activities such as exercise, stair climbing, getting up from a chair, and getting in and out of a car.

The presence or absence of knee swelling is an important part of the history because knee effusions (i.e., fluid in the knee joint) usually accompany internal derangement. An effusion also may be present with synovitis, osteoarthritis, inflammatory arthritis, fractures, infection, and neoplasms. Distinguishing between soft tissue swelling around the knee, synovial thickening, and a true knee effusion is critical (described in the following text). The timing or onset of the swelling is also important for determining the diagnosis. An acute cruciate or collateral ligament injury or osteochondral fracture usually presents with an acute hemarthrosis (occurring within an hour), whereas an effusion associated with arthritis tends to be more insidious in nature.

Reports of "locking" are common. In a younger patient, locking may be due to a displaced meniscal tear. In older patients who have degenerative arthritis, locking is often due to loose bodies. It is important to distinguish between true locking and diminished range of motion due to pain (so-called pseudolocking) because this distinction will determine which imaging studies are most appropriate.

Timing of the pain with activity is also important for making the correct diagnosis. Meniscus tears and ligament injuries leading to instability will be particularly troublesome with activities such as walking on uneven surfaces and stairs, movements requiring knee flexion, and pivoting. Osteoarthritis tends to be exacerbated by all load-bearing activities and relieved by rest.

The clinician also should explore the patient's exercise tolerance and ability to perform activities of daily living. These details may give insight into the severity of the injury and also will guide treatment. Important details include the use of ambulatory assist devices (e.g., a cane, crutches, walker, brace, or wheelchair), walking tolerance, and capability for other exercises (e.g., physical therapy).

A history of any previous treatments rendered also should be recorded. A patient's response to physical therapy, analgesics, nonsteroidal anti-inflammatory drugs, nutritional supplements (such as glucosamine and chondroitin), intra-articular injections of corticosteroids or hyaluronic acid derivatives, and any operative treatments will lend further insight into the accurate diagnosis and have implications for treatment once the diagnosis has been confirmed.

After obtaining a detailed history, the clinician should be able to formulate a differential diagnosis with a short list of potential conditions. This information should then allow the physician to concentrate on specific aspects of a focused physical examination that will lead to confirmation of the diagnosis.

**Figure 48-1** Assessment of coronal alignment.

## Physical Examination

### General

After a brief overall assessment of the patient, the physical examination should begin with observation of the patient's lower extremity coronal alignment and leg lengths. We prefer to have patients stand with their legs slightly apart while they face the examiner (Figure 48-1). A goniometer is then used to measure the varus/valgus alignment of the knees. Evaluation of leg lengths should be performed with step blocks of known sizes. The total height of the blocks needed to make the iliac crests level with the floor is equivalent to the leg length discrepancy (Figure 48-2).

Gait is examined next. Although a comprehensive discussion of gait analysis is beyond the scope of this chapter, all clinicians should routinely make a few basics observations when evaluating patients with a knee problem. Antalgic gaits (i.e., a shortened stance phase) and thrusts are commonly seen. Any disorder that causes lower extremity pain may cause an antalgic gait. Seen in the stance phase of gait, thrusts may be due to a progressive angular deformity as a result of degenerative changes or chronic ligamentous instability. Medial thrusts result from medial collateral ligament and/or posteromedial capsular laxity. Lateral thrusts arise from lateral collateral ligament or posterolateral corner laxity (Figure 48-3). Patients also may thrust into recurvatum (the so-called back-knee deformity) as a result of posterior capsular laxity or quadriceps weakness.

The patient should then transfer to the examination table for evaluation in a comfortable supine position. The examination should proceed with inspection and palpation prior to performing any provocative maneuvers. A pillow should be placed under the knee if full extension is not possible because of pain (e.g., as a result of fractures, displaced meniscus tears, or a large effusion). If the patient has no known pre-existing disease, the contralateral knee can serve as an adequate control. The lower extremity should

**Figure 48-2** The total height of the blocks needed to make the iliac crests level is equal to the length discrepancy.

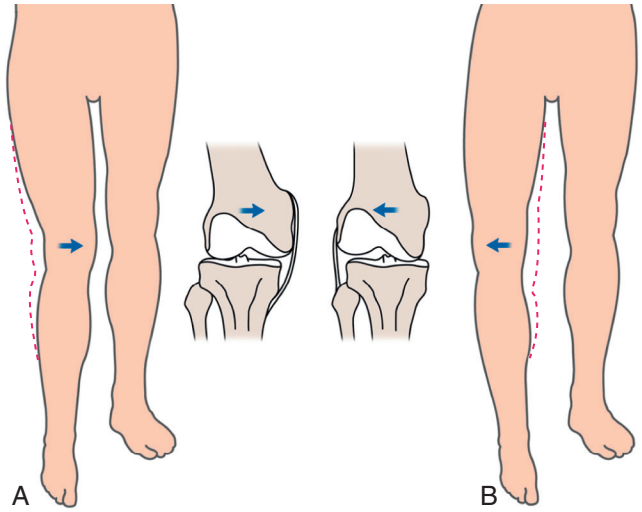

**Figure 48-3** The femur shifts medially during a medial thrust **(A)** and laterally during a lateral thrust **(B)**.

be inspected for any skin lesions, areas of ecchymosis, or surgical scars. Quadriceps atrophy should be noted, and a tape measure should be used to record thigh circumference. It is good practice to measure the thigh circumference at the same distance from the patella or joint line in each knee. The presence of an effusion, which will be seen as fullness or swelling in the suprapatellar pouch, should be noted. The effusion should be confirmed by ballottement of the patella (Figure 48-4). Small effusions will require "milking" of the fluid upward into the suprapatellar pouch, which will allow for quantification of the amount of fluid (Figure 48-5). The active and passive range of motion of both knees should be recorded with a goniometer.

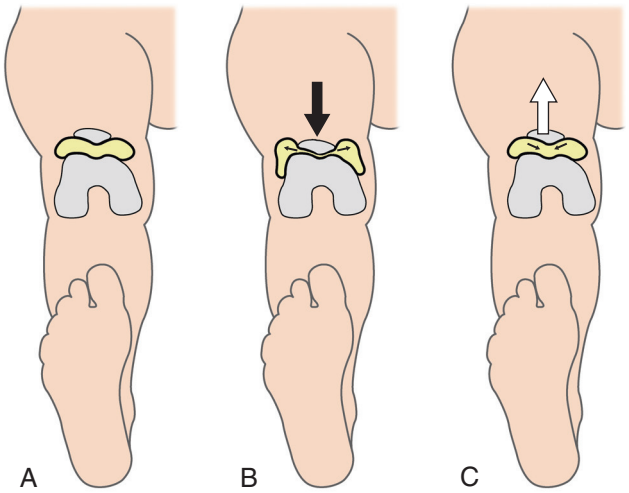

**Figure 48-4** Large effusions can be detected by "balloting" the patella with the knee in extension.

**Figure 48-5** Small effusions can be appreciated by the "milking" of fluid into the suprapatellar pouch.

The examiner should then proceed with palpation of all structures of the knee. It is important to perform this palpation in a systematic manner to ensure completeness. Palpation should be gentle but firm enough to detect subtle disease. Structures to be palpated include the quadriceps tendon, the patella (superior and inferior poles), the pes anserinus bursa, the medial (Figure 48-6A) and lateral (Figure 48-6B) joint lines, the origins and insertions of the collateral ligaments, the tibial tubercle, and the popliteal fossa. Fullness in the posterior knee may be indicative of a Baker's cyst.

## Ligaments

Injuries to the collateral or cruciate ligaments may lead to knee instability. It is important to mention that for each translational and rotational motion of the knee, both primary and secondary restraints exist. When a primary restraint is disrupted, motion will be limited by the secondary restraint. If a secondary restraint is injured and the

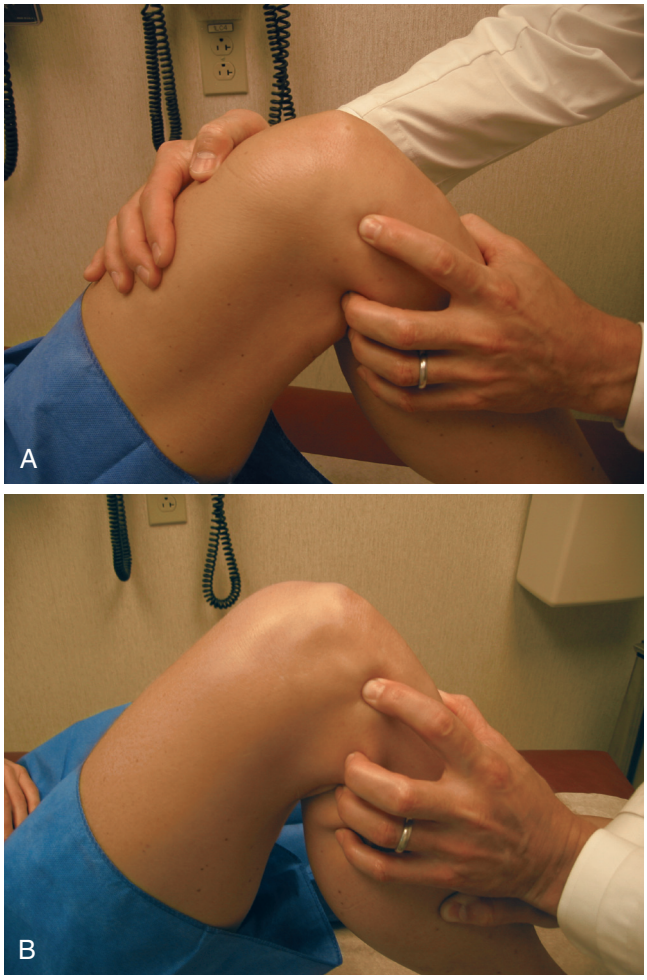

**Figure 48-6** Palpation of the medial **(A)** and lateral **(B)** joint lines.

**Figure 48-7** The anterior drawer test is performed by subluxating the tibia anteriorly with the knee in 90 degrees of flexion. The amount of anterior translation (mm) is noted. The endpoint is characterized as "soft" or "hard."

**Figure 48-8** The Lachman test is performed by applying an anterior force on the tibia while stabilizing the femur with the knee in 30 degrees of flexion.

primary restraint remains intact, then motion will not be abnormal. For example, the ACL is the primary restraint to anterior translation of the tibia, and the medial meniscus is the secondary restraint. ACL disruption will lead to a significant increase in anterior tibial translation. This translation will be increased if the patient underwent a prior medial menisectomy.[16]

The collateral ligaments can be examined with stress applied in the coronal plane. They should be examined in full extension, as well as in 30 degrees of flexion to remove the influence of the cruciate ligaments and the capsular restraints. With the patient in a supine position, a varus force is applied across the knee to test the lateral collateral ligament and a valgus force is applied across the knee to evaluate the medial collateral ligament.

The ACL is one of the most frequently injured structures in the knee. ACL insufficiency is also common in patients with advanced osteoarthritis. Common mechanisms of injury include a direct blow to the lateral side of the knee (the "clipping" injury in football causing the triad of medial collateral ligament, ACL, and medial meniscus injuries[17]), as well as noncontact injuries that occur during cutting, pivoting, and jumping.[18] Patients often report an audible "pop" accompanied by the acute onset of knee swelling. Multiple tests have been described to evaluate the ACL. The most sensitive tests for diagnosis of an ACL injury include the anterior drawer, Lachman,[19] and pivot-shift tests.[20,21] All three tests are performed with the patient in the supine position. The anterior drawer test is performed with the knee flexed to 90 degrees. The examiner places his or her hands on the posterior surface of the proximal tibia and subluxates the tibia anteriorly (Figure 48-7). Any gross movement of the tibia that is different from the contralateral side is considered abnormal. The Lachman test is performed with the knee in 30 degrees of flexion (to remove the contribution of secondary restraints). The examiner applies an anterior force on the tibia while stabilizing the femur with his or her contralateral hand. Any increase in anterior tibial translation relative to the contralateral side is considered abnormal (Figure 48-8). The pivot-shift test is performed with the knee in extension. The examiner holds the tibia in slight internal rotation and applies a

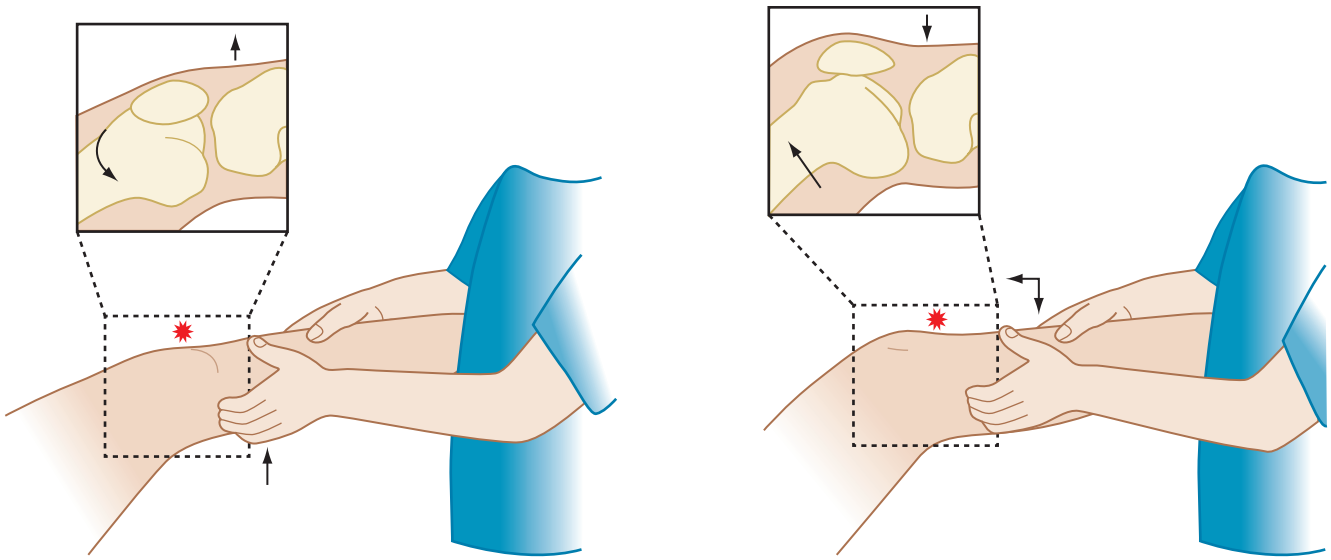

**Figure 48-9** The pivot shift test is positive if the tibia reduces with a "clunk" or a "glide" at 20 to 40 degrees of flexion.

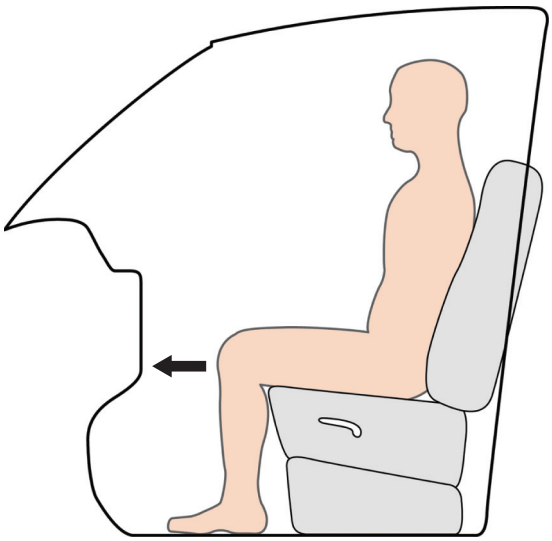

**Figure 48-10** An injury to the posterior cruciate ligament can occur when the tibia strikes the dashboard, causing the tibia to subluxate posteriorly on the femur.

**Figure 48-11** The posterior drawer test is performed by subluxating the tibia posteriorly with the knee in 90 degrees of flexion. The amount of posterior translation (mm) is noted. The endpoint is characterized as "soft" or "hard."

valgus stress while the knee is slowly flexed. This combination of forces should cause the tibia to subluxate anteriorly if the anterior cruciate ligament is injured. The test is positive if the tibia reduces with a "clunk" or a "glide" at 20 to 40 degrees of flexion (Figure 48-9).

The posterior cruciate ligament (PCL) is the strongest ligament in the knee,[22,23] and thus injuries to the PCL are usually a result of significant knee trauma. The "dashboard" injury is a common mechanism for PCL injury and occurs during a motor vehicle accident when the flexed knee strikes the dashboard (Figure 48-10). The PCL can be evaluated with the posterior drawer, posterior sag, and quadriceps active tests. All tests are performed with the patient in the supine position. The posterior drawer test is performed with the knee in 90 degrees of flexion. The examiner applies a posteriorly directed force to the tibia. Placement of one's thumb tips at the anterior joint line permits quantification of any abnormal translation (Figure 48-11). The posterior sag test is positive when the tibia subluxates posteriorly with the knee at 90 degrees of flexion. Loss of the medial tibial step-off at the joint line should alert the examiner to a PCL injury (Figure 48-12).[22] This test is usually positive in the chronic setting or after inducement of anesthesia in the acute setting. The quadriceps active test is performed with the knee in 60 degrees of flexion. The patient is asked to extend the knee while keeping his or her foot on the examination table. Reduction of the tibia will be seen in a positive test.[24]

Injuries to the PCL are often accompanied by injuries to the posterolateral corner, a complex structure that functions as both a static and a dynamic stabilizer of the knee.[23] It is composed of the lateral collateral ligament, the popliteofibular ligament, the popliteomeniscal attachment, the arcuate ligament, and the popliteus tendon and muscle.[25] Injuries to the posterolateral corner and/or the PCL can be examined with the "dial test" (Figure 48-13). The posterolateral corner structures restrain external rotation at 30 degrees of flexion, whereas the PCL restrains external rotation at 90 degrees of flexion. An increase of external rotation at 90 degrees of flexion without an increase in external rotation at 30 degrees of flexion suggests an isolated PCL injury. An increase of external rotation at 30 degrees of flexion without an increase at 90 degrees of flexion suggests an isolated injury to the posterolateral corner. Increased external rotation at both 30 and 90 degrees of flexion suggests combined PCL and posterolateral corner injuries.

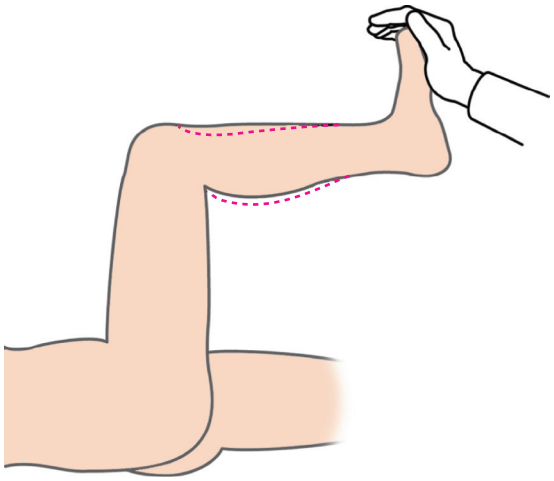

**Figure 48-12** The posterior sag test is positive when the tibia subluxates posteriorly with the knee at 90 degrees of flexion.

## Menisci

Traumatic and degenerative meniscal injuries are among the most common knee injuries. The menisci are considered the "shock-absorbing" cartilages of the knee and also provide rotational and translational restraint. The medial meniscus tends to be more bean-shaped and is both larger and less mobile than the lateral meniscus. The lateral meniscus tends to be more C-shaped. These anatomic differences have implications for the different injuries patterns seen in these two structures.

Meniscal tears usually occur with rotation of the flexed knee as it moves into extension. Tears of the medial meniscus are more common than tears of the lateral meniscus, likely because of the relative lack of mobility of the medial meniscus.[26] Patients frequently report "locking" and "clicking" or of something not being right with the knee, which usually results from displacement of the torn meniscus during motion. Common physical findings include pain with hyperflexion and with hyperextension, joint line tenderness, and an effusion. Many provocative tests have been described to diagnose meniscal tears. The McMurray[27] and Apley compression[28] tests are frequently performed, although they lack sensitivity and specificity. The flexion McMurray test is performed with the patient supine and the hip and knee flexed to 90 degrees. A compressive and rotational force is applied to the knee as it is moved from a flexed to an extended position. The test is positive if the patient reports pain (Figure 48-14). The Apley compression test is performed with the patient prone and the knee flexed to 90 degrees. When the test is positive, the patient will report pain with rotation of the tibia. An arthroscopic photograph in Figure 48-15 shows a tear in the posterior horn of the medial meniscus.

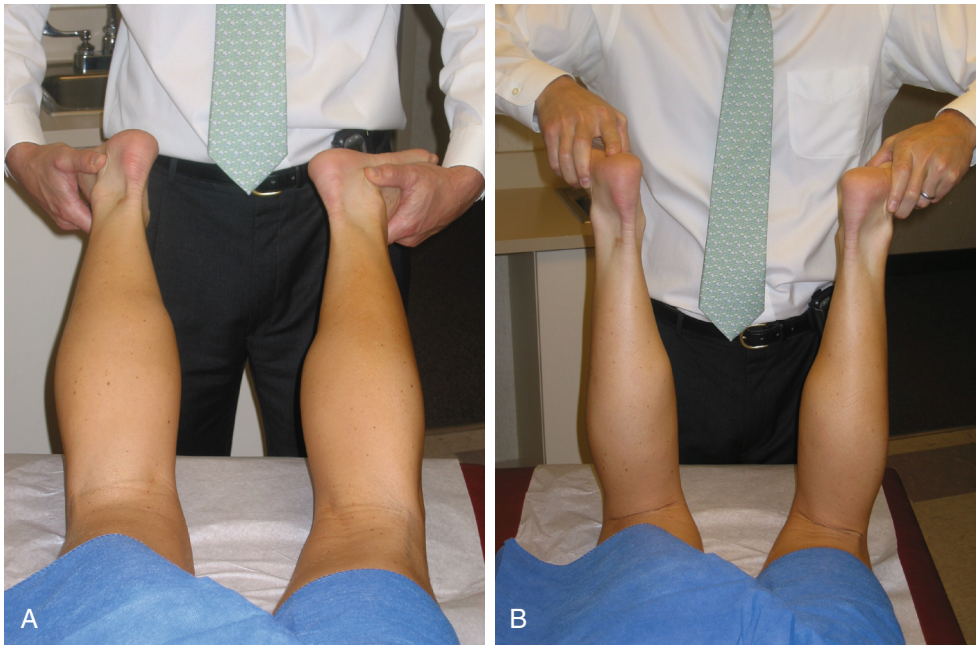

**Figure 48-13** The degree of tibial external rotation is measured in the "dial" test.

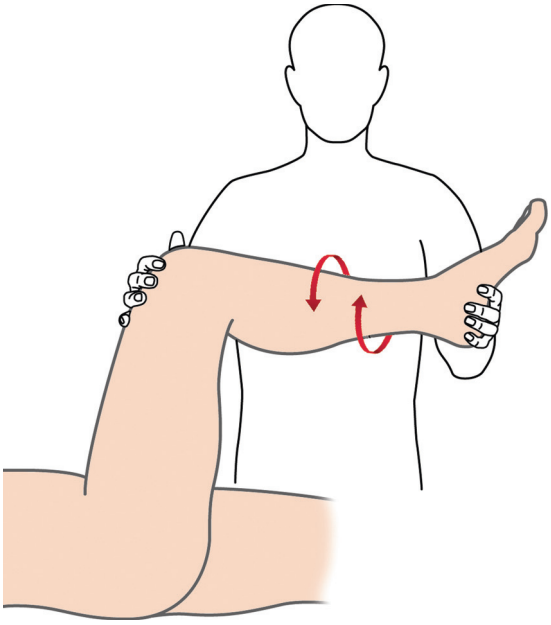

**Figure 48-14** A positive flexion McMurray test may indicate a torn meniscus.

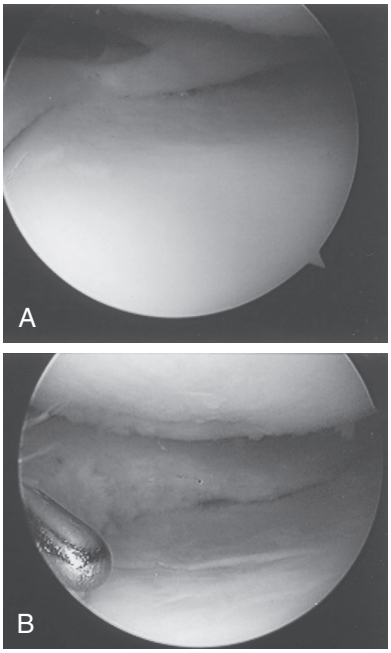

**Figure 48-15** An arthroscopic photograph of a tear in the posterior horn of the medial meniscus before **(A)** and after **(B)** debridement.

## Quadriceps Tendon

Injuries to the quadriceps tendon are most common in the sixth and seventh decades of life. Patients with systemic lupus erythematosus, renal failure, endocrinopathies, diabetes, and various other systemic inflammatory and metabolic diseases tend to be at a higher risk for these injuries. The occurrence of quadriceps tendon rupture after total knee arthroplasty is a rare complication (with an incidence of 0.1%), but when it occurs it is devastating.[29] Patients usually present with intense anterior knee pain after experiencing an eccentric quadriceps contraction during a fall or twisting

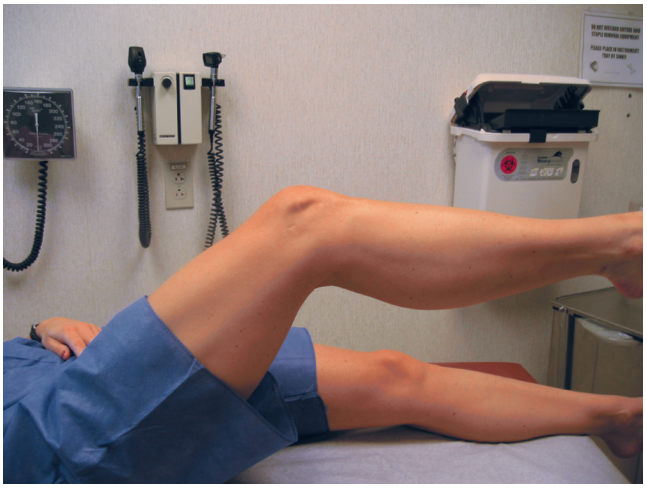

**Figure 48-16** An extensor lag due to a complete tear in the quadriceps tendon.

injury. Physical examination reveals a palpable defect in the tendon, an effusion resulting from hemarthrosis, and hypermobility of the patella. Patients usually will not be able to fully extend their knee (Figure 48-16).

## Patella Tendon

Problems with the infrapatellar tendon include tendonitis and rupture. Tendonitis is usually an overuse injury and is often associated with jumping, changes in activity level, and eccentric contractions during falls. Patients exhibit tenderness at their tibial tubercle or at the inferior pole of their patella. Rupture of the patella tendon usually occurs in patients younger than 40 years and is associated with chronic patella tendonitis. Patients usually present with anterior knee pain and the inability to extend their knee.

## Patellofemoral Pain

Persons who report having anterior knee pain are commonly seen by orthopedic surgeons. Anterior knee pain is more common in women and accounts for up to 25% of all sports-related knee injuries.[30] A variety of factors contribute to the biomechanics of the patellofemoral joint, including overuse, the depth of the trochlea, the shape of the patella, quadriceps strength, the line of pull of the quadriceps relative to the patella tendon (the Q angle), the length of the patella tendon, the shape of the femoral condyles, and the articular cartilage. Abnormalities of any of these factors may contribute to this pain syndrome, and successful treatment is possible only with correct identification of any contributing factors.

Physical examination of the patellofemoral joint begins with an analysis of coronal alignment of the knee because any valgus deformity may contribute to lateral subluxation. The height of the patella relative to the tibial tubercle should be noted (patella alta or baja). The J sign is present when the patella slides laterally at terminal extension, indicating excessive pull of the vastus lateralis. The vastus medialis obliquus is the primary stabilizer against lateral pull by the vastus lateralis. With the knee extended and the quadriceps relaxed, the examiner should make note of any

patellar tilt. Any crepitus, either audible or palpable, should be noted as well. Crepitus is common in persons with osteoarthritis. A Q angle greater than 15 degrees in women and greater than 8 to 10 degrees in men is considered abnormal.[30] Patellar mobility should be assessed using a quadrant system for passive mediolateral displacement of the patella relative to the trochlear groove. The normal patella should not be displaced medially or laterally beyond the second quadrant. Any abnormality in mobility may stem from changes in the tightness of the retinaculum. The apprehension test is performed by attempting to subluxate the patella with the knee in extension. The test is positive when it elicits pain and an unwillingness to allow the examiner to move the patella laterally (Figure 48-17).

**Figure 48-17** The apprehension test is positive when subluxation of the patella causes pain.

At the conclusion of the history and physical examination, the astute clinician should have formulated a short list of possible diagnoses. With this list in mind, the appropriate imaging studies can now be obtained. The goal of the initial imaging studies should be to confirm the diagnosis with the most appropriate and least-expensive study. Advanced imaging studies should not replace a thorough history and physical examination.

## Imaging

### Conventional Radiographs

Conventional radiographs are usually the first study obtained after knee injury and should be read in a systematic fashion. Soft tissues should be evaluated before examining the bony structures. Findings should be described in terms of radiolucent and radiopaque lines. Only after the findings have been described should the interpretation phase begin. Bypassing the description and proceeding directly to interpretation is a natural tendency, but if this tendency is followed, it is likely that certain findings will be missed or dismissed prematurely.

The basic radiographic evaluation of the knee consists of standing anteroposterior (AP) weight-bearing, lateral, and Merchant's views. The AP view permits evaluation of coronal alignment and the height of the tibiofemoral joint spaces. The normal coronal alignment of the knee should be 5 to 7 degrees of anatomic (tibiofemoral) valgus. The lateral tibiofemoral joint space should be wider than the medial tibiofemoral joint space in a normal knee. The presence of marginal osteophytes, joint space narrowing, subchondral sclerosis, and cystic change will be seen in the presence of osteoarthritis (Figure 48-18). Periarticular

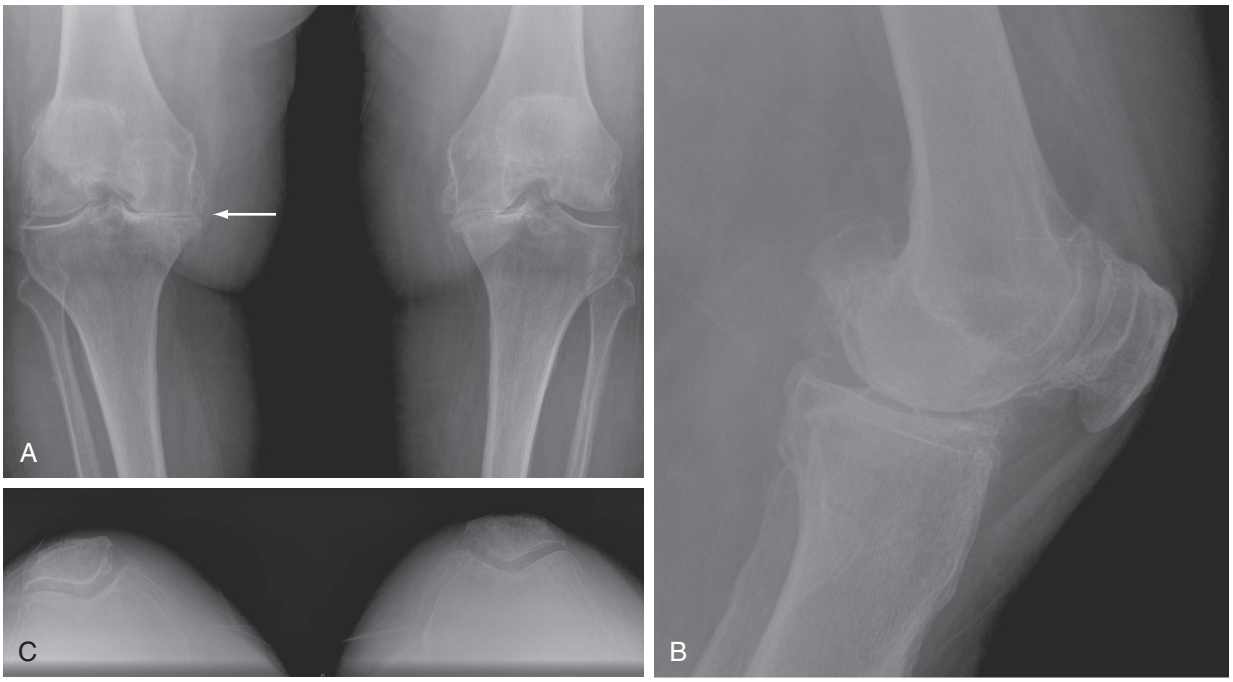

**Figure 48-18** Standing anteroposterior **(A)**, lateral **(B)**, and Merchant's **(C)** views of an osteoarthritic knee.

osteopenia, concentric joint space narrowing, and a paucity of osteophytes are commonly seen in persons with inflammatory arthritis (Figure 48-19). The lateral radiograph allows for evaluation of an effusion, patella tendon length, and the quadriceps tendon. The Merchant's view, which is taken tangential to the patellofemoral joint,[31] permits detection of patellofemoral arthritis and malalignment.

Additional views include a posteroanterior (PA) standing view with the knees flexed approximately 45 degrees, the tunnel or intercondylar notch view, and the 36-inch AP standing view of bilateral lower extremities. The flexed PA standing view is taken with the radiographic beam directed 10 degrees caudad from anterior to posterior, which permits evaluation of the posterior femoral condyles for joint space narrowing.[32] The tunnel view is obtained with the knee flexed and the radiographic beam directed inferiorly at an angle perpendicular to the tibial plateau. It is useful in detecting posterior tibiofemoral joint space narrowing, tibial spine fractures, loose bodies, and osteochondral lesions on the medial aspect of the femoral condyles. The 36-inch standing view is used for determining the mechanical axis of the lower extremity, as well for evaluating any deformity that may be present. The normal mechanical axis is a straight line joining the center of the hip, knee, and ankle joints. Surgeons use it for pre-operative planning and post-operative evaluation in total knee arthroplasty, as well for the planning of distal femoral and proximal tibia osteotomies in arthritis surgery.

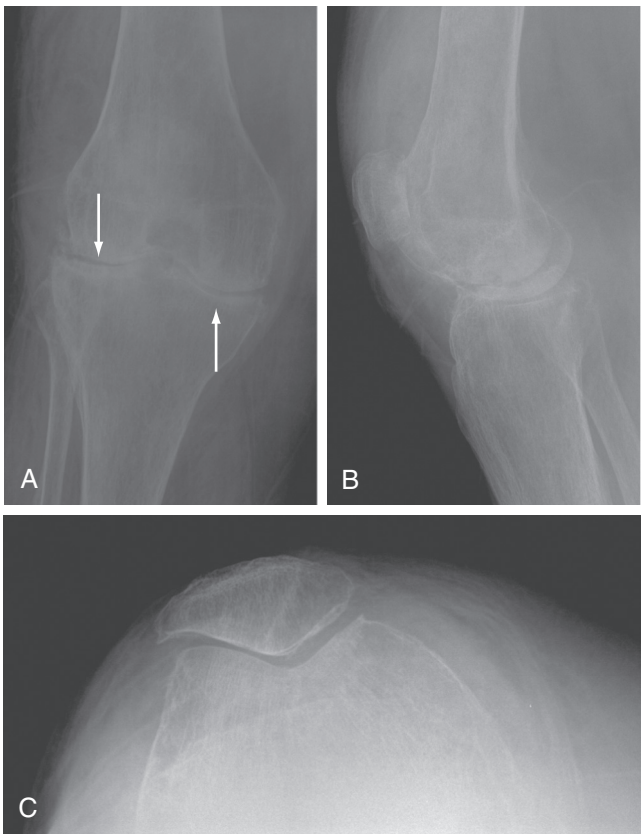

**Figure 48-19** Standing anteroposterior **(A)**, lateral **(B)**, and Merchant's **(C)** views of the knee in a patient with rheumatoid arthritis.

## Computed Tomography

CT has largely been replaced by MRI in evaluation of routine knee problems. CT is now used primarily for detection of bony tumors and in the trauma setting for detection of subtle fractures that are not easily visualized with conventional radiographs, as well as for a more thorough evaluation of intra-articular fractures. In cases of distal femoral or proximal tibia fractures, CT is used to help the surgeon plan operative treatment. CT is also used to assess axial alignment of the femoral and tibial components in cases of the painful total knee arthroplasty.[33,34]

## Ultrasound

The use of ultrasound has become more common in the diagnosis and treatment of knee disorders. Some practitioners use ultrasound routinely in both hospital and office settings to assist in arthrocentesis of the knee. Ultrasound is an attractive imaging modality because of its low cost, real-time capabilities, and portability. The ability to perform provocative maneuvers during sonography is particularly appealing. Ultrasound can easily and reliably detect joint effusions and popliteal cysts (Figure 48-20), as well as quadriceps and patella tendon disruptions. It has been reported that ultrasound can detect a 1-mm increase in joint fluid.[35]

## Nuclear Scintigraphy

Nuclear scintigraphy is very sensitive but not specific and is used to detect areas of increased osseous remodeling. It requires clinical correlation and should be used in conjunction with other imaging modalities. Technetium phosphate compounds are injected intravenously. Approximately 50% of the tracer is excreted by the kidneys, and the remainder is taken up in areas of increased osseous turnover. Imaging of the skeleton is typically performed 2 to 3 hours after injection because this delay allows for maximum contrast between the soft tissues and the skeletal structures while still providing for an adequate photon count.[36]

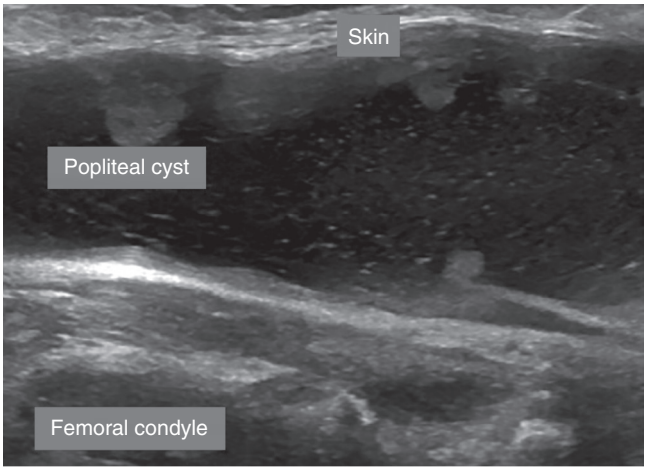

**Figure 48-20** This ultrasound image shows a large popliteal cyst in a patient with symptomatic knee osteoarthritis that was treated with aspiration and injection of corticosteroid.

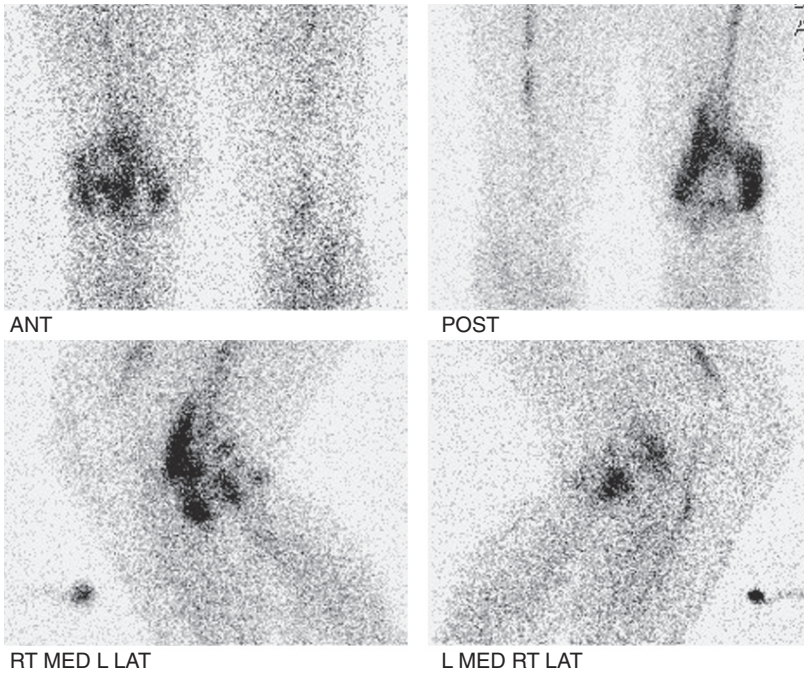

**Figure 48-21** A bone scan reveals increased uptake of radiotracer around the distal femur in this patient with an infected total knee arthroplasty and septic loosening of his femoral component. ANT, Anterior; L MED RT LAT, left medial right lateral; POST, posterior; RT MED L LAT, right medial left lateral.

Three-phase bone scanning can yield additional information. The three phases include an angiographic pool, followed by blood pool and bone imaging. The angiographic phases allows for detection of regional hyperemia. This technique has been reported to have greater specificity and can be used in cases of suspected osteomyelitis, osteonecrosis, stress fracture, and implant loosening.[36] It has been reported that increased radionuclide uptake can be seen for up to 12 to 18 months after total knee arthroplasty. Asymmetric uptake in one area around the prosthesis should raise the question of loosening or periprosthetic fracture (Figure 48-21).[37,38] The addition of labeled leukocytes to the technetium-99m sulfur colloid yields an 80% sensitivity and 100% specificity for diagnosing infection.[39]

### Magnetic Resonance Imaging

MRI has supplanted many imaging modalities because of its direct multiplanar capabilities and superior soft tissue contrast. Although conventional radiographs remain the gold standard for defining osseous structures, MRI provides excellent visualization of articular cartilage, the cruciate ligaments, the collateral ligaments, the patella tendon, the quadriceps tendon, and the menisci (Figure 48-22). It is also highly sensitive for detecting bone marrow edema (contusion), stress fractures, and mass lesions. Use of the "two-slice touch" rule has improved the sensitivity and specificity of MRI in accurately diagnosing meniscal tears. This rule classifies a meniscus as torn if two or more MR images show abnormal findings and as possibly torn if only one MR image shows an abnormal finding. Using fast spin-echo imaging, the sensitivity and specificity for diagnosing medial and lateral meniscal tears was 95% and 85%, and 77% and 89%, respectively, translating to a positive predictive value of 91% to 94% for medial meniscus tears and 83% to 96% for lateral meniscus tears.[40]

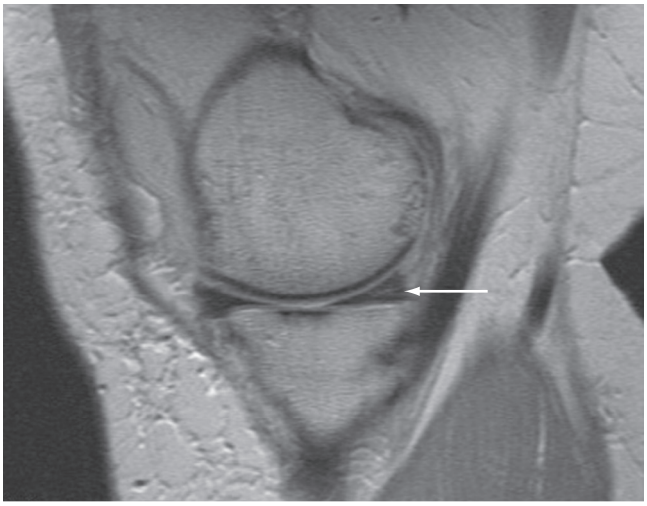

**Figure 48-22** This sagittal MRI shows linear signal change extending to the meniscal surface consistent with a tear *(arrow)* in the posterior horn of the medial meniscus.

## Common Disorders in the Differential Diagnosis of Knee Pain

### General

Though many diseases exist that may involve the knee, a limited number of them are encountered frequently. In

evaluating knee pain, the clinician should be familiar with osteoarthritis, rheumatoid arthritis, inflammatory arthritis associated with the seronegative spondyloarthropathies, tears of the menisci, ligaments, and tendons, osteochondritis desiccans, osteochondral fractures, fractures, referred pain from the hip (such as with slipped capital femoral epiphysis in adolescents), vascular claudication, neurogenic claudication, complex regional pain syndrome, sarcoma, metastases, and infection.

### Bursitis

The prepatellar bursa lies between the retinaculum and the subcutaneous fat and runs from the patella to the tibial tubercle. The bursa may become inflamed and fill with fluid when exposed to a direct blow or repetitive microtrauma (e.g., kneeling). Patients with prepatellar bursitis present with anterior knee pain upon flexion and a fluctuant mass over the anterior knee. If the area becomes warm, tender to palpation, and erythematous, septic bursitis should be ruled out with aspiration. The pes anserinus bursa, located over the insertions of the sartorius, gracilis, and semitendinosus muscles on the proximal medial tibia, also can be a source of knee pain if it is inflamed.

### Neoplasia

Tumors in the area of the knee are often diagnosed after trauma prompts medical evaluation. Pain at night, pain at rest, and constitutional symptoms should alert the clinician to consider the appropriate workup. Some of the benign tumors seen in the area of the knee include enchondroma, pigmented villonodular synovitis, osteochondromatosis, and giant cell tumor. Malignant tumors seen in the area of the knee include but are not limited to metastases, osteosarcoma, Ewing's sarcoma, chondrosarcoma, and malignant fibrous histiocytoma.

### Popliteal Cysts

A popliteal cyst, originally called Baker's cyst, is a synovial fluid-filled mass located in the popliteal fossa. The most common synovial popliteal cyst is considered to be a distension of the bursa located beneath the medial head of the gastrocnemius muscle. Usually, in an adult patient, an underlying intra-articular disorder (osteoarthritis) is present. In children, the cyst can be isolated and the knee joint can be normal. Patients usually present with episodic posterior knee pain.[41] The diagnosis is made by ultrasonography or MRI. Treatment options include benign neglect, aspiration, surgical excision, or removal of the underlying disease process (arthritis) with knee arthroplasty.

## HIP PAIN

### History

Obtaining an accurate history is an important initial step in formulating a differential diagnosis for patients who present with hip pain. In general, more conditions should be considered in the differential diagnosis for hip pain than for knee pain, because the hip is a common site for referred pain from lumbosacral and intrapelvic disease. A detailed, comprehensive history will direct the clinician to a focused physical examination.

Most patients who present with hip disease report having pain. It is important to define the exact location of the pain because "hip" pain may refer to discomfort in the groin, lateral thigh, or buttock. Pain in the groin or medial thigh region is usually due to hip disease and is believed to arise from irritation of the capsule and/or synovial lining.[42] Pain generated in the lumbosacral spine may be referred to the buttocks and/or lateral thigh.[43] Lateral thigh pain may stem from so-called "trochanteric bursitis" (usually abductor tendonitis) as well. Activities or positions that aggravate and relieve the pain should be explored. The severity, frequency, and patterns of radiation of the pain also should be evaluated. It is not uncommon for knee pain to be generated from the hip joint. Metastatic and primary tumors that occur in the pelvic and proximal thigh regions should always be included in the differential diagnosis. Intrapelvic disease from the prostate, seminal vesicles, hernias, ovaries, gastrointestinal system, and vasculature also should be considered.[44,45]

Knowledge of the patient's general level of functioning is important, because this information will lend insight into the severity of disease and may influence treatment. Patients with hip disease may have difficulty trimming their toenails, donning shoes and socks, and using stairs. Walking tolerance and use of assist devices also should be recorded. The Harris Hip Score and Western Ontario and McMaster Universities (WOMAC) Osteoarthritis Index are two rating scales that are widely used to assess function in this patient population.[46,47]

The patient should be asked about any hip problems that he or she encountered in childhood. Diseases such as developmental dysplasia, slipped capital femoral epiphysis, Legg-Calvé-Perthes disease, polio, and trauma may lead to osteoarthrosis later in life.[48-50] The patient should be asked about any treatment rendered for these diseases as well.

Osteoarthritis and inflammatory arthritis are two common causes of hip pain. In general, pain from osteoarthritis is exacerbated by activity and relieved by rest. Mild arthritis of the hip may not become symptomatic until a certain activity level is reached. Stiffness (usually from synovitis) is also commonly reported with both degenerative and inflammatory arthritis. When the hip pain continues despite a trial of rest, an underlying inflammatory or infectious process should be considered.

Any previous treatments for hip pain should be discussed. The patient's response to nonsteroidal anti-inflammatory medications, nutritional supplements (such as chondroitin and glucosamine), physical therapy, corticosteroid injections, local anesthetic injections, hyaluronic acid injections, ultrasound, and operative interventions should be recorded. Lastly, a more general medical history should be explored. The physician should be aware of alcoholism, neuromuscular disorders, smoking history, and general support systems.

### Physical Examination

The physical examination of the patient with hip pain begins as the clinician observes the patient for the first time.

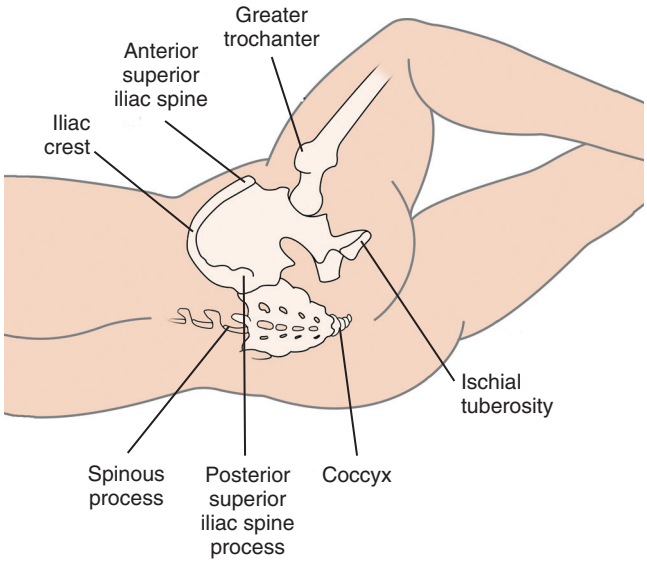

**Figure 48-23** The bony landmarks on the pelvis that can be palpated during physical examination.

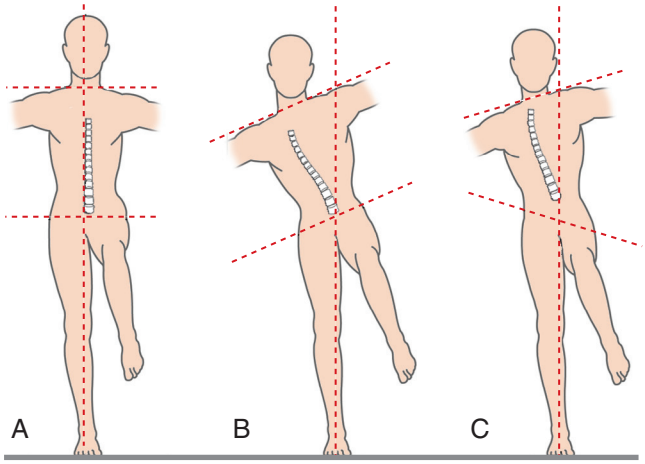

**Figure 48-24** Physical examination of abductor function: **A,** Normal single-legged stance. **B,** Positive Trendelenburg lurch and negative Trendelenburg's sign. **C,** Positive Trendelenburg lurch with pelvic obliquity and leaning over the involved hip to shift the body's center of gravity.

Ease of rising from a chair, postures, and walking speed all provide insight into the extent of a patient's disability. A general evaluation of the patient's spine, lower extremity alignment, and leg lengths is performed next. With the examiner behind the patient, the spine is examined for coronal and sagittal balance. The patient is asked to touch his or her toes. A rib hump indicates the presence of scoliosis. Any gross deformity of the spine will alert the examiner to the potential of a pelvic obliquity and resultant leg length discrepancy.

The overall coronal alignment of the lower extremities is evaluated next. If a leg length discrepancy is detected, blocks can be used, as discussed previously, to determine the amount of apparent inequality. If the leg length discrepancy is due to a fixed pelvic obliquity from lumbosacral disease, blocks may not be able to level the pelvis. Previous surgical scars in the area of the hip are noted. Palpation of the bony landmarks (iliac crest, anterior superior iliac spine, posterior superior iliac spine, ischial tuberosity, coccyx, spinous processes, and greater trochanter) should be performed (Figure 48-23). The femoral neck is located approximately three fingerbreadths below the anterior superior iliac spine.

A basic evaluation of gait should be performed. Although gait analysis is a complex science, all clinicians should feel comfortable evaluating patients for common abnormalities. The patient with hip pain may present with an antalgic gait. The severity of the limp should be classified as mild, moderate, or severe. Mild limps can only be detected by trained observers. Moderate limps will be noticed by the patient. A severe limp will be readily apparent and have a significant impact on the speed of ambulation. Common causes of a limp include pain and abductor (gluteus medius and gluteus minimus) weakness; differentiating between these two causes of limp is an important part of the physical examination.

The patient with abductor dysfunction will likely have an abductor or Trendelenburg lurch.[51] With a Trendelenburg lurch, the patient compensates for abductor dysfunction by leaning over the involved hip to shift the body's center of gravity in that direction (Figure 48-24). If the patient has a Trendelenburg lurch, we proceed to evaluate for Trendelenburg's sign. A positive Trendelenburg's sign occurs when the pelvis tilts toward the unsupported side during one-legged stance. This test is best performed with the examiner behind the patient. Causes of abductor weakness are numerous and may include a contracted or shortened gluteus medius, coxa vara, fracture, dysplasia, neurologic conditions (e.g., superior gluteal nerve injury, radiculopathy, poliomyelitis, myelomeningocele, and spinal cord lesions), and slipped capital femoral epiphysis.

The patient is then asked to lay supine on the examination table. The range of motion of both hips should be evaluated by recording flexion, extension, adduction, abduction, internal rotation in extension, and external rotation in extension. Hip extension is best evaluated with the patient in the prone position. Normal range of motion values include 100 to 135 degrees for flexion (the knee should be flexed to relax the hamstrings), 15 to 30 degrees for extension, 0 to 30 degrees for adduction, 0 to 40 degrees for abduction, 0 to 40 degrees for internal rotation, and 0 to 60 degrees for external rotation. Motion is often limited in cases of deformity (such as limited internal rotation in slipped capital femoral epiphysis) and advanced osteoarthritis. Internal rotation and abduction are usually the first motions to be limited in osteoarthritis. Motion will be painful in patients with synovitis as well. Areas that are painful should be palpated.

A series of special tests can be performed to evaluate for subtle muscle contractures and limitation of motion. The presence of a hip flexion contracture is common in patients with moderate to severe hip disease and can be quantified with the Thomas test (Figure 48-25).[52] This test is performed by having the patient bring his or her thighs to the chest while in the supine position. This maneuver allows for flattening of the spine, and the hip to be evaluated is allowed to extend to neutral. If the patient is unable to reach neutral, the amount of flexion contracture is recorded. The Ober test measures tightness of the iliotibial band. The patient lies on the unaffected side and the examiner helps

the patient abduct the hip with the hip extended and the knee flexed to 90 degrees. The leg is slowly released from abduction to neutral, and the hip will remain abducted if contracture of the iliotibial band occurs. Ely's test will detect a tight rectus femoris. The knee is passively flexed with the patient in the prone position. If the rectus femoris is tight, the ipsilateral hip will spontaneously flex. If the rectus femoris is normal, the hip will remain flush with the examination table.

Patients occasionally report a "snapping" sensation in their hip. Although it may be difficult for the clinician to reproduce snapping, patients may be able to demonstrate it by flexing and internally rotating their hip. Extra-articular causes of hip snapping include a thickened iliotibial band snapping over the greater trochanter, the iliopsoas tendon gliding over the iliopectineal eminence, the long head of the biceps tendon rubbing on the ischial tuberosity, and the iliofemoral ligament rubbing on the femoral head. Intra-articular causes of snapping hip syndrome include loose bodies and large labral tears.

**Figure 48-25** In the Thomas test, a hip flexion contracture is measured by flexing the contralateral hip to eliminate compensatory lumbar lordosis. The ipsilateral hip is then allowed to extend with gravity. The angle between the examination table and the thigh is the degree of flexion contracture.

In addition to using blocks with the patient standing, leg lengths can be measured while the patient is in the supine position (Figure 48-26). The *apparent* leg length is the distance from the umbilicus to the medial malleolus. The *true* leg length is measured from the anterior superior iliac spine to the medial malleolus. Pelvic obliquity and abduction/adduction of the hip will create an apparent leg-length discrepancy.

Sacroiliac disease should be included in the differential diagnosis of hip pain. Although multiple provocative tests have been described to elicit sacroiliac disease, the FABER test (also known as Patrick's test) can help distinguish between hip and sacroiliac joint disease. With the patient supine, the clinician has the patient place his/her hip in the flexion, abduction, and externally rotated position. The clinician then presses the flexed knee and the contralateral anterior superior iliac spine toward the floor. Pain in the buttocks suggests sacroiliac joint disease, whereas pain in the groin points to hip disease. If the sacroiliac joint is implicated, it is recommended that multiple other provocative tests be performed. It has been shown that by using a combination of the distraction, thigh thrust, compression, sacral thrust, Gaenslen's, and FABER tests, sacroiliac joint disease is the likely pain generator when three or more of the tests are positive.[53,54]

The acetabular labrum is drawing attention as a previously underappreciated cause of hip pain. Clinical presentation of a labral tear of the acetabulum may be variable, and the diagnosis is often delayed. Patients usually see multiple providers before the diagnosis is confirmed. In a series of 66 patients with arthroscopically confirmed tears of the acetabular labrum, 92% reported groin pain, 91% had activity-related pain, 71% reported pain at night, 86% described the pain as moderate to severe, and 95% had a positive impingement sign. The authors recommended that a diagnosis of acetabular labral tear be suspected in young, active patients reporting groin pain with or without trauma.[55] The positive

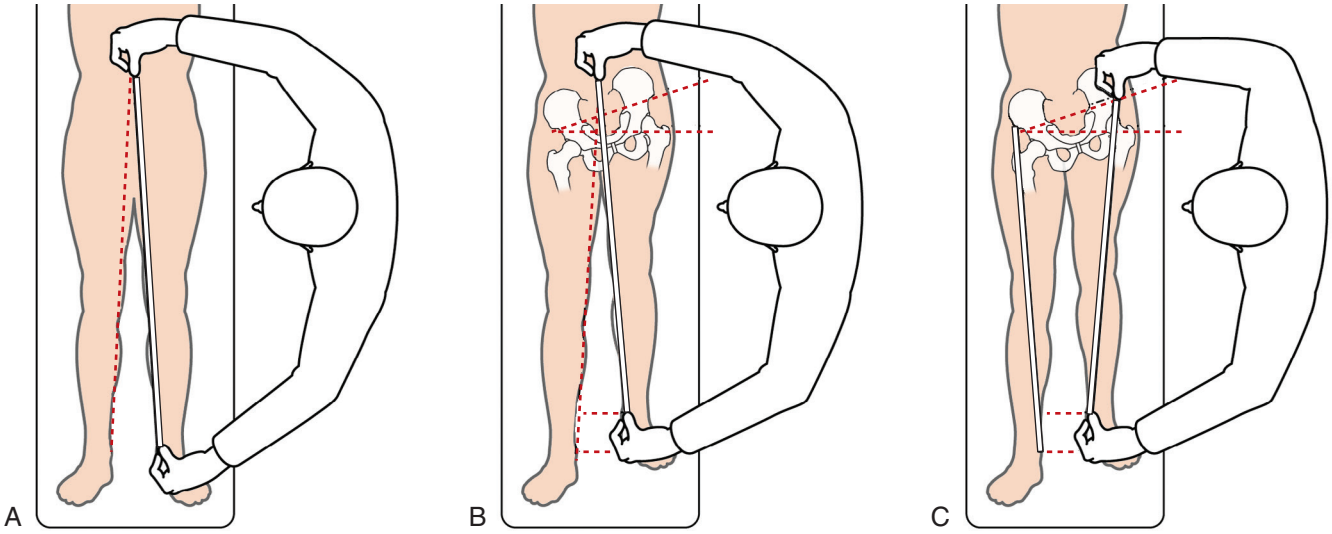

**Figure 48-26** Measurement of leg lengths. **A,** The apparent leg length is the distance from the umbilicus to the medial malleolus. **B,** Pelvic obliquity causing an apparent leg-length discrepancy. **C,** The true leg length is the distance from the anterior superior iliac spine to the medial malleolus.

impingement test helps confirm the diagnosis of a labral tear. The test is positive if the patient experiences groin pain with the hip flexed, adducted, and internally rotated. The positive predictive value of this test has been shown to range from 0.91 to 1.00 in six different studies.[56-61]

A thorough evaluation of the neurovascular system should be completed after the musculoskeletal portion of the physical examination for the hip or knee is completed. This evaluation should include palpation or Doppler evaluation of the femoral, popliteal, dorsalis pedis, and posterior tibial arteries, as indicated. Strength testing with resisted isometric movements for each muscle in the lower extremity is performed, with 5 being normal strength, 4 being full motion against gravity and against some resistance, 3 being fair motion against gravity, 2 being movement only with gravity eliminated, 1 being evidence of muscle contraction but no joint motion, and 0 being no evidence of contractility. Sensation in the lower extremity should be evaluated by assessing for light touch and/or appreciation of pin prick in a dermatomal distribution. Patellar and ankle reflexes should be tested. Lastly, the examiner should test for any abnormal clonus and Babinski reflexes as indicated.

## Imaging

### Conventional Radiographs

Plain radiographs remain the primary diagnostic imaging tool for the evaluation of hip disease. All other imaging modalities should be viewed as complementary to conventional radiographs. Our standard screening series include a low AP pelvis (Figure 48-27), an AP hip (Figure 48-28), a frog-lateral view, and a cross-table lateral view. The frog-lateral view provides a lateral of the proximal femur and is useful for detecting femoral head collapse (as seen in osteonecrosis; Figure 48-29). Numerous other special radiographs of the hip may be obtained, some of which include Judet 45-degree oblique views and the false profile view. Judet views allow easier visualization of the anterior (obturator oblique) and posterior (iliac oblique) columns. The false profile view allows evaluation of the anterior bony coverage of the femoral head in cases of acetabular dysplasia. Developmental dysplasia of the hip is common, and we do not recommend the routine use of any special views prior to referral to an orthopedic surgeon (Figure 48-30).

### Computed Tomography

CT is used for assessment of acetabular fractures, acetabular nonunion, femoral head fractures, subtle femoral neck fractures, neoplasia, and bone stock in the revision total hip arthroplasty setting. Because of its limited soft-tissue

**Figure 48-28** An anteroposterior hip demonstrating the characteristic concentric joint space narrowing, paucity of osteophytes, and periarticular osteopenia seen in rheumatoid arthritis.

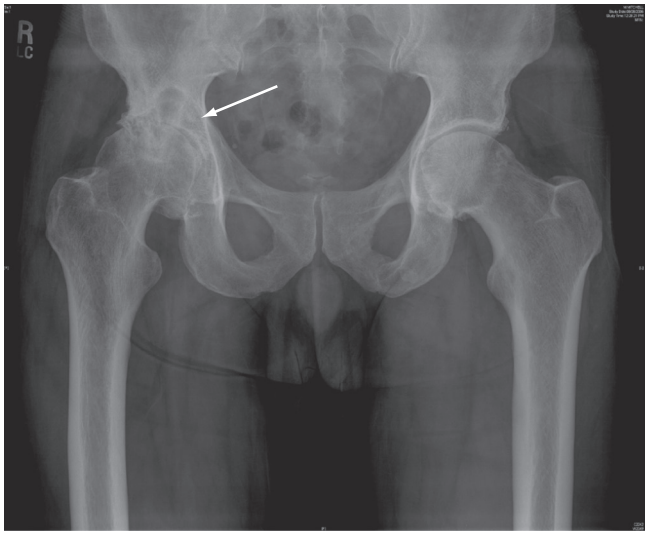

**Figure 48-27** An anteroposterior pelvis demonstrates the characteristic joint space narrowing, cystic changes, and osteophytes seen in osteoarthritis.

**Figure 48-29** A frog-lateral radiograph demonstrating femoral head collapse from osteonecrosis.

contrast, CT has largely been replaced by MRI for detailed evaluation of the soft tissues around the hip.

### Nuclear Scintigraphy

The role of bone scanning in the evaluation of hip disease is similar to its role in the assessment of knee pain. It should always be used in conjunction with other imaging modalities because of its limited specificity (Figure 48-31).

**Figure 48-30** An anteroposterior hip radiograph demonstrates osteoarthrosis from developmental dysplasia. The up-sloping lateral edge of the acetabulum is characteristic for developmental dysplasia of the hip.

### Magnetic Resonance Imaging

MRI provides unprecedented detail of the soft tissues around the hip joint. MRI is now commonly used for diagnosis of osteonecrosis, labral disease, neoplasia, effusion, synovitis, loose bodies, tendonitis, transient osteoporosis of the hip, occult femoral neck fractures, bone edema, gluteus medius tendon avulsions, and nerve injury. MR arthrography of the hip joint is useful for identifying gluteus medius tendon avulsion after total hip arthroplasty (Figure 48-32) and for detecting labral tears. One study showed a 92% sensitivity for the detection of labral tears using MR arthrography.[62] Delayed gadolinium-enhanced MRI of cartilage, a technique designed to measure early arthritis in the hip joint, is now being used clinically in the management of hip dysplasia.[63] Despite the tremendous diagnostic capabilities of MRI, its ability to detect bony disease is limited. As such, conventional radiographs remain the imaging modality of choice for the screening of hip disease.

### Ultrasound

The use of ultrasound for the diagnosis and treatment of hip disorders is common. Some practitioners use ultrasound routinely in the office setting. Common hip conditions that are often managed with ultrasound-guided injections and/or aspirations include osteoarthritis, septic arthritis (Figure 48-33), iliopsoas tendonitis, adverse local tissue reaction associated with metal-on-metal articulating total hip arthroplasties, and trochanteric bursitis.

### Hip Arthrography

Hip arthrography is useful for detecting avulsions of the gluteus medius tendon from the greater trochanter and for

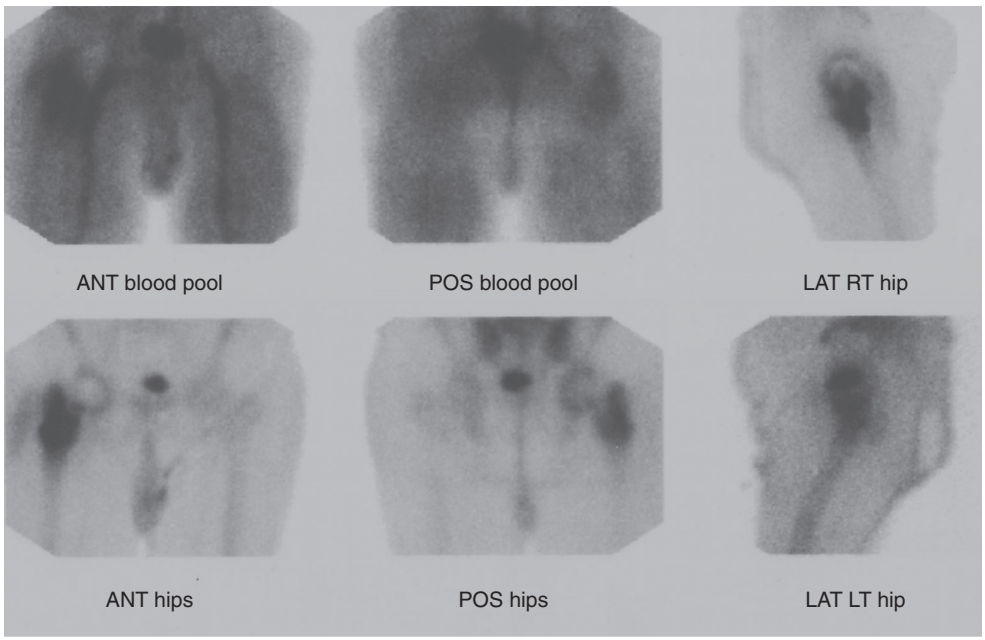

**Figure 48-31** This bone scan shows increased radiotracer uptake at the proximal femur. The patient presented with activity-related thigh pain 1-year after undergoing primary cementless total hip arthroplasty. History, physical examination, and conventional radiographs suggested failure of osseointegration. At the time of surgery, the femoral component was found to be grossly loose. ANT, Anterior; LAT, lateral; LT, left; POS, posterior; RT, right.

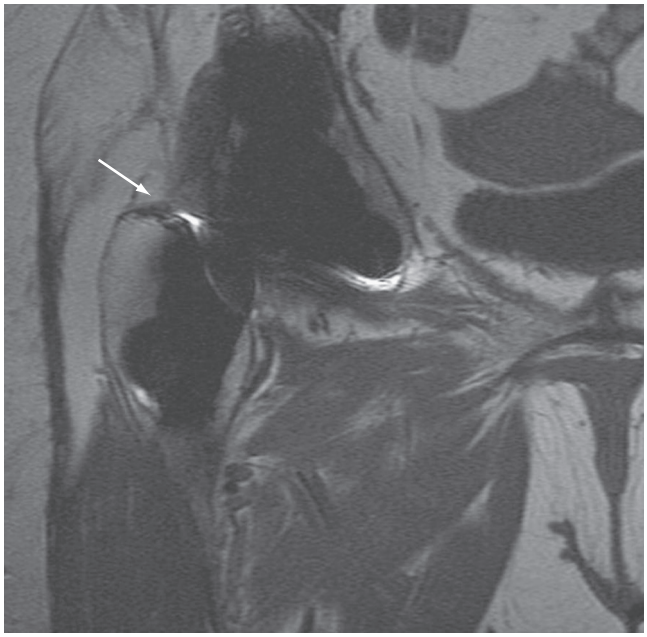

**Figure 48-32** This short tau inversion recovery coronal MRI shows a complete avulsion of the gluteus medius tendon from its insertion on the greater trochanter. Note the signal change along the lateral aspect of the greater trochanter, consistent with accumulation of intra-articular gadolinium at the site where the gluteus medius tendon should be.

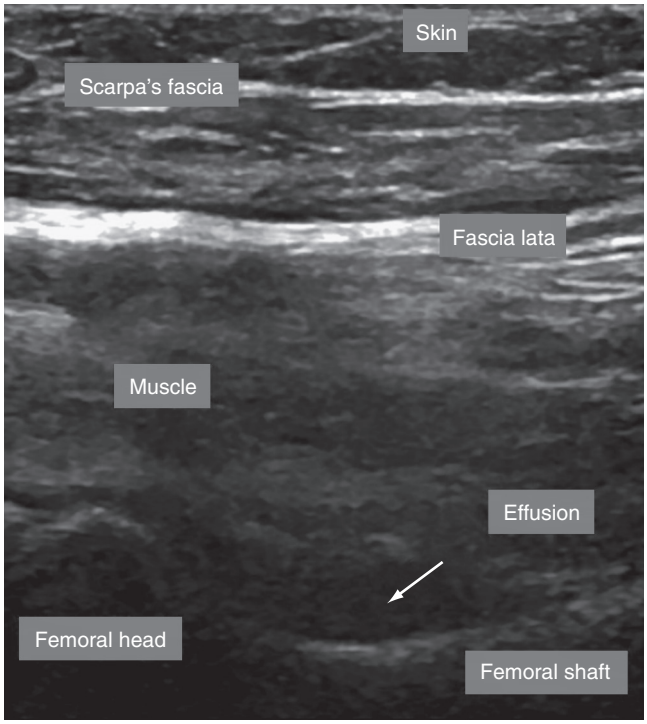

**Figure 48-33** This ultrasound image depicts a small hip effusion in a 9-year-old girl who was evaluated for toxic synovitis versus septic arthritis. Ultrasound images from the asymptomatic, contralateral hip showed comparable amounts of fluid, arguing against septic arthritis.

differentiating intra-articular hip disease from lumbosacral disease. In one study, intra-articular anesthetic injection was 90% accurate in predicting intra-articular disease as confirmed by hip arthroscopy.[64] Anesthetic arthrogram of the hip has shown a 95% positive predictive value and a 67% negative predictive value for pain relief after total hip arthroplasty in patients with concurrent hip and lumbar osteoarthritis.[65]

## Common Disorders in the Differential Diagnosis of Hip Pain

Common causes of hip pain are numerous, and a detailed discussion of these causes is beyond the scope of this chapter. The differential diagnosis of hip pain should include osteoarthrosis (most frequently from developmental dysplasia, Legg-Calvé-Perthes disease, or slipped capital femoral epiphysis), inflammatory arthritis, osteonecrosis, fractures (acetabulum, femoral head, femoral neck, intertrochanteric, or subtrochanteric), trochanteric bursitis, femoroacetabular impingement, tears of the acetabular labrum, transient osteoporosis of the proximal femur, infection, snapping hip syndrome, osteitis pubis, neoplasia (osteosarcoma, chondrosarcoma, pigmented villonodular synovitis, osteochondromatosis, malignant fibrous histiocytoma, or metastases), inguinal hernia, or referred pain (lumbosacral spine, sacroiliac joint, prostate, seminal vesicles, uterus, ovaries, and lower gastrointestinal tract). This list can be efficiently narrowed down by taking a detailed history, performing a comprehensive examination of the musculoskeletal and neurovascular systems, and obtaining the appropriate imaging studies.

CHAPTER 49

# Foot and Ankle Pain

Mark D. Price • Christopher P. Chiodo

**KEY POINTS**

- The differential diagnosis for foot and ankle pain is vast. Localizing symptoms by anatomic region helps narrow this differential.
- On physical examination, most structures in the foot and ankle are immediately subcutaneous and readily palpable.
- Beyond medications, useful nonoperative treatments include bracing, shoe wear modification, orthoses, and physical therapy.
- Most surgical procedures in foot and ankle surgery fall into one of the following categories: arthrodesis, arthroplasty, corrective osteotomy, ostectomy, tendon débridement and transfer, and synovectomy. Patient compliance and soft tissue integrity are important factors when considering surgery.
- Advances in medical management now make joint-sparing procedures possible in many patients with inflammatory arthritis who previously would have required arthrodesis.

Foot and ankle pain are independent risk factors for locomotor instability, impaired balance, and increased risk for falling, as well as compromised functional activities of daily living.[1-5] Foot and ankle pain affect approximately one in five middle-aged to older individuals. Interference with daily activities occurs in one-half to one-third of affected individuals but is rarely disabling outside the context of rheumatoid arthritis. Foot and ankle pain are significantly more common in women, a finding that has been attributed to gender-specific footwear.

## ETIOLOGY

The differential diagnosis of foot and ankle pain is vast and includes disorders of tendons, ligaments, muscle, bone, joints, periarticular structures, nerves, and vessels, as well as referred pain (Table 49-1).

One of the most common cause of pain of the foot and ankle is osteoarthritis (OA). Although OA is the most prevalent joint disease, its pathophysiology remains poorly understood. Ankle and foot OA results from damage and loss of the articular cartilage, which can cause inflammation, stiffness, pain, swelling, deformity, and limitation of function, such as walking or standing. Osteophyte formation can also lead to mechanical impingement. In the foot, OA most commonly occurs in the big toe (hallux), the midfoot, and ankle. In the early stages, pain may occur only at the beginning and at the end of an activity, but while the condition progresses it can become constant and occur even while the individual is at rest.

The ankle is a complex joint that is subject to enormous force during daily activities and in sports, especially running. It is also the joint most commonly injured in the human body and is subject to sprains, fractures, and chondral injuries. This combination of factors predisposes the ankle joint to degenerative changes, although the risk is lower than in other weight-bearing joints, such as the hip and knee. The ankle also rarely develops arthritic changes without an identifiable cause. The most common cause of ankle OA is trauma, including both fracture and ligamentous injury with subsequent chronic instability. Other causes of OA are abnormal mechanics (flat feet and high-arched feet) and, less commonly, systemic diseases such as hemochromatosis.

Foot and ankle pain is the presenting complaint in approximately 15% to 20% of newly diagnosed rheumatoid arthritis (RA) patients.[6] Further, of those patients already diagnosed with RA, the prevalence of foot and ankle involvement has been estimated to be greater than 90%.[7]

The clinician should begin the evaluation of the rheumatoid foot and ankle with a thorough history and physical examination. The location, timing, and duration of symptoms can help to establish a specific diagnosis and guide the subsequent course of treatment. Radiographs and advanced imaging modalities provide useful adjuncts to the evaluation of specific foot and ankle pathologies.

The treatment of the rheumatoid foot and ankle is aimed at both alleviating pain and preserving function (i.e., maintaining the ambulatory status of the patient). Initial nonoperative treatment includes medical management, physical therapy, shoe wear modification, orthotics, and bracing. These measures provide substantial relief for many patients. For recalcitrant symptoms, surgical intervention may be necessary. Most surgical procedures fall into one of the following general categories: arthrodesis (joint fusion), arthroplasty (joint replacement), corrective osteotomy, ostectomy, and synovectomy (joint or tendon).

## FUNCTIONAL ANATOMY AND BIOMECHANICS

The ankle, or tibiotalar joint, is composed of the articulation between the foot (talus) and the lower leg (distal tibia and fibula). Its primary motion is plantar flexion and dorsiflexion in the sagittal plane. In addition, the articulation

**TABLE 49-1** Differential Diagnosis of Foot and Ankle Pain

| |
|---|
| **Tendon, Ligament, and Muscle** |
| Ankle or foot ligament tear or attenuation |
| Chronic joint instability secondary to ligament compromise |
| Joint impingement caused by ligamentous tear and/or hypertrophy |
| Sinus tarsi pathology |
| Achilles tendon pathology |
| Achilles tendon rupture |
| Plantar fasciitis |
| Posterior tibial tendon dysfunction (usually with adult acquired flatfoot) |
| Flexor hallucis longus tenosynovitis and stenosis |
| Tibialis anterior tendon tear |
| Peroneus tendon pathology |
| **Bone** |
| Acute fractures of the ankle or foot |
| Stress fractures |
| Freiberg's infraction (osteonecrosis of the second metatarsal head) |
| Osteonecrosis of talus and navicular |
| Sesamoid bone pathology |
| Metatarsal overload (metatarsalgia) |
| **Joint** |
| Osteoarthritis |
| Gout |
| Rheumatoid arthritis |
| Other inflammatory arthritides |
| Charcot neuroarthropathy |
| Osteochondral lesion of the talus |
| Joint impingement (bone, synovitis, or ligamentous hypertrophy) |
| Hammer toe, claw toe, and mallet toe deformities |
| Hallux rigidus |
| **Nerve Compression** |
| Tarsal tunnel syndrome |
| Anterior tarsal tunnel syndrome (involvement of deep peroneal nerve under the superficial fascia of the ankle) |
| Morton's neuroma |
| Vessels |
| Vasculitis |
| Atherosclerosis |
| Compartment syndrome |
| Neuropathic and Referred Pain |
| Neuropathy |
| Spinal pathology |

between the distal tibia and fibula allows a lesser amount of internal and external rotation to occur in the axial, or transverse, plane.

The foot may be loosely divided into three anatomic regions: forefoot, midfoot, and hindfoot. The forefoot consists of the toes and metatarsal bones, along with the metatarsophalangeal (MTP) and interphalangeal (IP) joints. The tarsometatarsal (TMT) joints connect the forefoot to the midfoot, which comprises the three cuneiform bones, the navicular, and the cuboid. Finally, the hindfoot, located below the ankle, consists of the talus and calcaneus. The joints of the hindfoot include the talocalcaneal (subtalar), talonavicular, and calcaneocuboid articulations.

Forefoot and midfoot motion is primarily plantarflexion and dorsiflexion in the sagittal plane, with some secondary pronation and supination in the coronal plane and abduction/adduction in the axial plane. Motion in the hindfoot is primarily composed of inversion/eversion in the coronal plane, with secondary internal/external rotation in the axial plane and plantarflexion/dorsiflexion in the sagittal plane.

Knowledge of these anatomic divisions is important because radiographs often demonstrate polyarticular disease in patients with RA. An intimate understanding of the local anatomy is an essential resource for the physician to establish an accurate diagnosis and formulate an appropriate treatment plan.

## DIAGNOSTIC EVALUATION

### Physical Examination

The physician should begin a thorough physical examination of the foot and ankle with gait analysis, even if by simply observing the patient enter the examination room. Normal human gait is divided into two phases. The stance phase is the weight-bearing portion of the gait cycle and comprises roughly 60% of normal walking. This phase begins with heel-strike and then extends through foot-flat to toe-off motion. Meanwhile, the swing phase of gait extends from toe-off to heel-strike and comprises the remaining 40% of the gait cycle.

Patients with an "antalgic" gait pattern will have a shortened stance phase on the side of the affected limb, while they attempt to more quickly transfer their weight to the nonpainful limb. In addition to an antalgic gait, foot and ankle pain often results in the avoidance of ground contact with the painful part of the foot. A further problem noted in stance phase is dynamic collapse of the medial longitudinal arch, most apparent at foot-flat and toe-off.

During the swing phase of gait, a "steppage" gait may be noted. This type of gait is characterized by excessive hip and knee flexion, to allow the foot to clear the ground in the setting of a footdrop. In patients with RA, it may be caused by attritional rupture of the anterior tibialis tendon, which is the main dorsiflexor of the ankle.

After gait analysis, the physician inspects the foot and ankle, both with the patient in the sitting and standing position. The location of swelling is usually well correlated with the joint(s) involved (e.g., the ankle vs. the talocalcaneal joint). Deformity should also be noted. Commonly seen deformities in patients with RA include hallux valgus, or bunion (Figure 49-1); hammertoes; and flatfoot deformity (characterized by hindfoot valgus/forefoot abduction). Callosities develop over regions of increased pressure and are associated with deformity and fat pad atrophy. Rheumatoid nodules can appear anywhere on the foot but are often found in areas of repetitive trauma (i.e., at the site of irritation from a tight shoe counter). Similarly, ulcerations may appear in areas of increased pressure or repeated injury. Finally, wear patterns on shoes should also be noted. As Hoppenfeld observed[8]: "A deformed foot can deform any good shoe; in fact, in many cases the shoe is a literal showcase for certain disorders."

After inspection of the foot and ankle, the physician performs range-of-motion analysis. Passive range of motion of the ankle is normally between 10 and 20 degrees of dorsiflexion and 40 and 50 degrees of plantarflexion. Normal hindfoot inversion and eversion are approximately 20 and 10 degrees, respectively. The first MTP joint should have

**Figure 49-1** Clinical photograph of hallux valgus deformity.

approximately 45 degrees of "plantarflexion" (flexion) and 70 to 90 degrees of "dorsiflexion" (extension). Deviations from these norms should be noted as part of the standard workup.

Next, the physician thoroughly palpates the foot and ankle. The dorsum of the foot and ankle has little overlying musculature. As such, many of the bones and tendons are immediately subcutaneous and a great deal of information can be gained from palpating these structures. It is helpful to palpate the foot and ankle by anatomic location (i.e., forefoot, midfoot, hindfoot, and anterior and posterior ankle).

In the forefoot, the first metatarsal head and MTP joint can be palpated at the base of the hallux, at the medial aspect of the "ball" of the foot. Proceeding laterally, the physician can then sequentially palpate the lesser metatarsal heads and MTP joints. In patients with RA, such palpation often reveals tenderness, synovitis, and bursal swelling. In the second and third MTP joints, sagittal plane instability often results from attenuation of the plantar joint capsule. This condition can be appreciated by gently translating the second and third toes dorsally.

In the hindfoot, the calcaneus is readily palpable, and its various parts can be palpated individually. A stress fracture should always be considered in patients with RA. Further, tenderness over the posterior aspect of the bone may indicate Achilles tendon pathology, while pain over the medial tubercle (palpable on the medial plantar surface) may indicate plantar fasciitis. Tenderness over the "sinus tarsi" of the hindfoot (located laterally, just anterior and distal to the tip of the fibula) usually indicates talocalcaneal joint pathology. Finally, posteromedial tenderness may be secondary to tenosynovitis, posterior tibial tendinosis, and tarsal tunnel syndrome (usually secondary to adjacent tenosynovitis).

In the ankle joint proper, tenderness over the anterior joint line usually correlates with ankle joint pathology including arthritis, synovitis, impingement, and osteochondral defect (OCD).

A more detailed description of these conditions and their correlation with anatomic location is provided later in the chapter and in Table 49-2.

**TABLE 49-2** Anatomic Basis of Common Causes of Foot and Ankle Pain

| Location | Pathology/Dysfunction |
|---|---|
| Forefoot | Arthritis/synovitis<br>Hallux valgus<br>Hammertoes, claw toes, and mallet toes<br>Morton's neuroma<br>Metatarsophalangeal arthritis/synovitis/instability<br>Osteonecrosis of the second metatarsal head (Freiberg's) |
| Midfoot | Arthritis/synovitis, stress fracture, osteonecrosis (navicular) |
| Hindfoot | Arthritis/synovitis<br>Hindfoot valgus deformity<br>Stress fracture<br>Plantar fasciitis |
| Anterior ankle | Arthritis, synovitis, impingement, osteochondral defect |
| Central ankle | Osteochondral lesion<br>Stress fracture |
| Posterior ankle | Achilles tendinitis/tendinosis<br>Retrocalcaneal bursitis<br>Achilles rupture<br>Stress fracture |
| Posterolateral ankle | Peroneal tendinitis, tear, instability |
| Posteromedial ankle | Posterior tibial tendinitis/dysfunction<br>Flexor hallucis longus/flexor digitorum longus tendinitis<br>Tarsal tunnel syndrome |

## IMAGING

Despite the abundant availability of advanced imaging modalities such as magnetic resonance imaging (MRI) and computed tomography (CT), radiographs remain the imaging mainstay in the evaluation of foot and ankle pain. Weight-bearing images should be obtained whenever possible because joint space narrowing and deformity may not be apparent in nonweight-bearing images. Standard images consist of weight-bearing anteroposterior, lateral, and oblique views of the foot and anteroposterior, mortise, and lateral views of the ankle. Further radiographic findings of RA include periarticular erosions and osteopenia.

MRI provides reliable imaging of soft tissue structures and can be a useful tool in the evaluation of the rheumatoid foot and ankle. Early in the course of RA, MRI allows one to look for signs of the disease such as synovitis, tenosynovitis, periarticular edema, and bursitis.[9] Later, MRI is useful in assessing disease progression and extent of joint involvement, as well as in distinguishing between tendon rupture and tendinitis/tendinopathy (Figure 49-2).

CT scan[10] and nuclear scintigraphy[11] are also used in the evaluation of foot and ankle pain. For example, either method can be quite helpful in post-operative evaluation in fusion surgery. Ultrasound is gaining utility as a method to

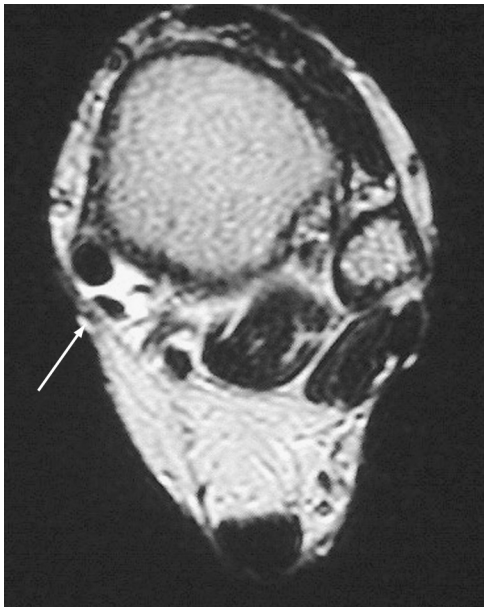

**Figure 49-2** Axial magnetic resonance image of ankle demonstrating posterior tibial tendon degeneration and synovitis *(arrow)*.

evaluate joint inflammation as well as tendon integrity. There is no radiation involved, and the procedure is now frequently performed in the office setting. However, the results are sometimes operator and technique dependent with minimization of artifacts being of utmost concern. In addition, ultrasound may be difficult to use in pre-operative planning because important landmarks are often not included.[12]

Anesthetic arthrograms are an extremely useful adjunct in diagnosing foot and ankle pain in patients with RA. Given the complex and crowded geometry of the foot and the propensity of RA to affect multiple joints and tendons, it is often difficult to determine whether the pain is articular and, if so, which joint is symptomatic. With an anesthetic arthrogram, a mixture of steroid, anesthetic, and contrast material is injected under fluoroscopic guidance into a suspect joint. This allows the clinician to more precisely determine whether or not the injected joint is a significant pain generator. Again, this is especially helpful in the foot and ankle, where multiple joints are in close proximity and may be simultaneously diseased.[13]

## DIFFERENTIAL DIAGNOSIS OF ANKLE PAIN

From a diagnostic standpoint, it is useful for the clinician to conceptualize ankle pain on the basis of anatomic location. This approach applies to patients with virtually any form of ankle or foot pain, and RA will be used to illustrate how to formulate a differential diagnosis and treatment plan while advances in medical management temper disease and "allow" patients to develop other, non-inflammatory disorders.

### Anterior Ankle Pain

Anterior ankle pain, in patients both with and without RA, is most often the result of intra-articular pathology. Anteriorly, the ankle joint is not shielded by the malleoli and is immediately subcutaneous. Further, the anterior extensor tendons are typically not prone to the development of tendinitis and tendinosis.

In early RA, synovitis can cause anterior joint line pain, swelling, and tenderness. Clinically, this results in symptoms of "impingement." Specifically, patients will note pain with ankle dorsiflexion, such as when they walk up stairs or an incline. On physical examination, there may be anterior tenderness and/or pain with terminal passive dorsiflexion. Anterior osteophyte formation may produce even more pronounced impingement symptoms, although such osteophytes are more commonly seen with OA and longstanding ankle instability.

### Central Joint Pain

Two other causes of central ankle pain, stress fracture and OCD, should be considered. Stress fractures are commonly seen in patients with periarticular and generalized osteopenia. An OCD is a focal defect in the articular cartilage and subchondral bone. These lesions are encountered more commonly in patients without inflammatory arthritis. In the setting of RA, their presence may represent an early manifestation of RA or a separate pathologic process.

### Posterior Joint Pain

Posterior ankle pain usually originates from the Achilles tendon, its insertion onto the calcaneal tuberosity, and two associated bursae in this region. The Achilles tendon is the largest tendon in the body but lacks a true synovial lining. As such, isolated Achilles tendinitis is uncommon. In most instances, Achilles pain results from degenerative tendinosis, with or without an overlying tendinitis. Although associated spur formation is common, it is important to remember that Achilles spurs are a manifestation of a disease process. As such, surgeries directed at spur excision also frequently entail tendon débridement and reconstruction, as well as tendon transfer.

The Achilles tendon is associated with two bursae. The "retrocalcaneal" bursa is a larger structure that lies deep to the Achilles. Inflammation of this structure often accompanies Achilles tendinitis/tendinosis. It may also be irritated by an enlarged posterior superior calcaneal tuberosity, sometimes referred to as "Haglund's" deformity. Less commonly, a more superficial, immediately subcutaneous bursa can develop with irritation from ill-fitting shoes with a tight counter ("pump bump").

### Medial and Lateral Ankle Pain

As with anterior, central, and posterior ankle pain, the origin of medial or lateral ankle pain is also anatomically based.

On the medial side, pain directly over the medial malleolus should alert the clinician to the possibility of a stress fracture. Pain anterior to the medial malleolus is usually articular in nature. Pain posterior to the medial malleolus is often caused by inflammation and/or degeneration of the posteromedial flexor tendons. These include the posterior tibial tendon and the flexor hallucis longus and flexor

digitorum longus tendons. The posterior tibial tendon is the largest and strongest of the posteromedial flexor tendons. Its primary function is to invert the hindfoot and thus support the medial longitudinal arch of the foot. Long-standing synovitis and dysfunction of this tendon may ultimately lead to collapse of the arch and the development of an acquired flatfoot deformity.

On the lateral side of the ankle, pain directly over the lateral malleolus may be caused by a stress fracture. This is especially relevant in the setting of hindfoot valgus and a flatfoot, which will increase fibular loading. Similar to the medial side, pain anterior to the lateral malleolus is usually articular in nature. Finally, pain posterior to this lateral malleolus is usually indicative of peroneal tendon pathology. In patients with RA, the peroneal tendons may be affected by tenosynovitis, longitudinal "split" tears, and chronic tendon instability. With the latter, the tendons sublux over the posterolateral edge of the fibula, causing pain as well as attritional tearing.

## DIFFERENTIAL DIAGNOSIS OF FOOT PAIN

Typically, the forefoot is the most common site of involvement early in the course of diseases such as RA but also can occur in patients with gout and OA.[14] The pathogenesis of forefoot pain and deformity in the rheumatoid forefoot is inflammation and progressive synovitis that eventually leads to a capsular distention at the MTP joints and attenuation of the plantar plates.[15] Eventually it progresses to loss of collateral ligament stability and, finally, destruction of the articular cartilage and bone (Figure 49-3A and B). Clinically, this typically manifests as hallux valgus and dorsal subluxation or dislocation of the lesser toe MTP joints with a hallux valgus deformity, and presents in the patient as metatarsalgia.

In the lesser MTP joints, such loss of stability leads to progressive deformity secondary to ligamentous attenuation combined with the standard forces on the forefoot. Muscle imbalance and dorsiflexion forces during the toe-off phase of gait cause progressive subluxation and even dorsal dislocation of the MTP joints. With these changes, the metatarsal head is prone to forming keratotic skin lesions that can ultimately ulcerate. Muscle imbalance can also lead to the development of painful hammertoe and claw toe deformities that can exert a plantar-directed force that further exacerbates symptomatic metatarsalgia. Lesser MTP joint subluxation has been reported to be as high as 70%, with a concomitant incidence of pressure sores in approximately 30% of those patients.

In the hallux, RA can cause both articular erosions and loss of capsular integrity that often results in the development of a hallux valgus deformity, or bunion (see Figure 49-1). The progression of this deformity may be further accelerated by loss of support from the adjacent lesser MTP joints. The incidence of hallux valgus deformity in patients with RA has been estimated to be as high as 70%.

The midfoot is a less common site of involvement in the rheumatoid foot. Radiographically there can be erosions; however, the prevalence of symptoms is often quite low. The most frequent site of involvement is the first tarsometatarsal (TMT) joint. The symptoms seen here, though, may not be from rheumatoid synovitis per se, as seen in the forefoot. Rather, pain may also be due to hindfoot and hallux valgus deformities that lead to increased stresses across the TMT joint. Eventually this increased stress can lead to dorsiflexion of the first TMT joint and resultant lesser toe TMT joint abduction and dorsiflexion, thereby leading to pain in the dorsomedial midfoot. In addition, progressive biomechanical changes can lead to OA of the midfoot TMT joints, causing discomfort and pain with weight bearing.

The three joints of the hindfoot (talonavicular, talocalcaneal, and calcaneocuboid) are commonly affected by RA. Although these joints are affected at different rates, the overall prevalence of hindfoot involvement in patients with RA is between 21% and 29%. The talonavicular joint is most often affected, followed by the talocalcaneal and then calcaneocuboid joints. Further, the hindfoot becomes more symptomatic and involved the longer the duration of RA. The incidence of hindfoot deformity in patients diagnosed with RA for less than 5 years has been estimated to be 8% and increases to 25% in patients with RA for longer than 5 years.[16] Clinically, patients with talocalcaneal or calcaneocuboid involvement will complain of lateral hindfoot pain. Meanwhile, arthritis and synovitis of the talonavicular joint are manifested by dorsal or medial pain.

The deformity most often seen in patients with hindfoot RA is an acquired flatfoot deformity, characterized by heel valgus and forefoot abduction. This usually results from articular deformity and instability, but may also be caused by tenosynovitis and tendinosis of the posterior tibial tendon, the main supporter of the longitudinal arch of the foot.

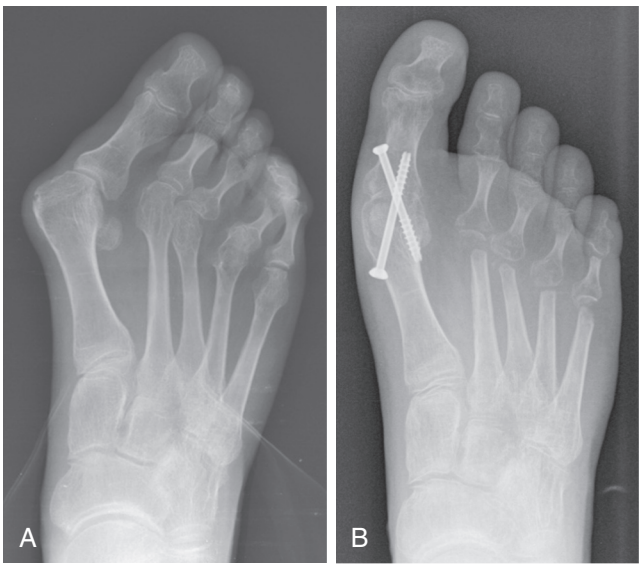

**Figure 49-3** Pre-operative **(A)** and post-operative **(B)** anteroposterior radiograph of hallux valgus deformity with lesser metatarsophalangeal joint erosions treated by fusion and lesser metatarsal head resections.

## NONOPERATIVE TREATMENT

Medical management remains the cornerstone of treatment for many forms of foot and ankle arthritis. In fact, many of the current recommendations for operative treatment

may soon be modified given the alteration of disease progression with current medical regimens for RA.[17] The most common medical management still consists of nonsteroidal anti-inflammatory drugs (NSAIDs), steroids, and disease-modifying anti-rheumatic drugs (DMARDs) and, more recently, biologic therapies. Although each of these drug classes has done much to alleviate patient suffering, they are not without impact on the surgical management of rheumatic disease. There is concern about lower fusion rates in the setting of NSAIDs and increased infection rates in the setting of steroids or DMARDs.[18,19] Moreover, patients who have been on chronic steroids are at risk for post-operative adrenal insufficiency and may require perioperative corticosteroids.[20] Close communication and collaboration between the rheumatologist and surgeon are essential to good outcomes.

Footwear modification can often have profound benefits for patients. Shoes should be examined in the clinic to be sure that they can accommodate a patient's deformity. Patients often feel best in shoes with a deep, wide toe-box, a firm heel counter, and soft heel. Well-constructed walking or jogging shoes usually provide sufficient room for mild to moderate deformities. It is helpful to provide patients with a list of suitable manufacturers when making such recommendations.

Often it is necessary to prescribe a custom orthotic insert for those with more moderate deformities. Typically the insole of the shoe must be removed to make room for the orthotic. Again, most walking or jogging shoes will suffice. In general, custom orthotics can be divided into rigid, semi-rigid, and softer accommodative devices. Rigid and semi-rigid orthotics are usually used to correct supple deformities and should be used with caution in patients with RA.[21] More commonly, patients benefit from accommodative orthotics (i.e., orthotics made of softer material that can be molded to "accommodate" a deformity).[22] These can then be further modified by incorporating a "relief" under a deformity, thereby further unloading it. When referring patients to a specialist for orthotics, it is best to provide the orthotist with a prescription that includes the patient's precise diagnosis (e.g., RA or OA with metatarsalgia), as well as the type of orthotic and any modifications desired (e.g., a "custom accommodative orthotic with a relief under the lesser metatarsal heads").[23]

Finally, injections of a mixture of anesthetic and corticosteroid to areas of inflammation or bursitis are useful to treat both inflammatory and non-inflammatory conditions affecting the foot and ankle. In the foot and ankle, however, such injections must be judiciously used. Most important, injections into and around tendons should be avoided. Because of the forces associated with weight bearing and ambulation, these tendons are under substantial load. The injection of a corticosteroid directly into or even near a tendon can adversely affect the biomechanical properties of the tendon and can ultimately lead to rupture.[24] A further precaution is to avoid corticosteroid injections into the lesser MTP when there is evidence of joint instability (manifested by valgus or varus deviation on radiographs or sagittal plane instability on physical examination). Such injections can lead to further attenuation of the joint capsule and can result in frank joint dislocation.

## OPERATIVE TREATMENT

If symptoms persist despite nonoperative management, surgical intervention should be considered. Two important factors must be taken into account when deciding whether or not to proceed with surgery. First, the soft tissues and vascular status must be carefully assessed. Both may be compromised and could negatively affect outcome. Second, the ability of patients to comply with the post-operative regimen (e.g., the ability able to use crutches and not bear weight if necessary) must be considered. Even limited noncompliance can lead to a poor outcome, especially in fusion surgery.

As noted earlier, most surgical procedures fall into one of the following categories: arthrodesis (joint fusion), arthroplasty (joint replacement), corrective osteotomy, ostectomy, and synovectomy (joint or tendon).

### Arthrodesis

Arthrodesis remains a surgical cornerstone for the rheumatoid foot and ankle. With an arthrodesis procedure, the two sides of the joint are roughened with a burr or small chisel. Next, the two bones to be fused are compressed and fixed together, usually with one or more screws (see Figure 49-3B). In the weeks and months after surgery, the body is "tricked" into thinking that there is a fracture present at the fusion site and heals this with bone. As such, the two bones become one and are considered fused. Fusion surgery offers reliable pain relief in the majority of patients. One obvious concern with fusion surgery is the loss of motion. For the patient, however, this usually results in only mild functional compromise. Further, to the untrained eye, the patient has a remarkably minor change in gait.

Commonly performed fusions in patients with RA include ankle arthrodesis, isolated hindfoot fusions, triple arthrodesis, midfoot arthrodesis, and arthrodesis of the first MTP joint. A triple arthrodesis involves fusion of the talocalcaneal, talonavicular, and calcaneocuboid joints. Together, these joints allow coronal plane motion and thereby are most important when an individual is walking on uneven ground.

Arthrodesis is still commonly performed in patients with RA of the ankle. If there is minimal deformity and no loss of bone stock, ankle fusion surgery may be performed arthroscopically or through a "mini open" approach. These techniques involve less soft tissue dissection and stripping, thereby minimizing loss of bony perfusion. Nevertheless, the time period for which the patient must avoid bearing weight (from 6 to 12 weeks) remains the same. The success rate of ankle fusion surgery in patients with RA is generally 85% or greater. Although the osteopenia associated with the disease can compromise fixation, it can also theoretically enhance fusion because less sclerotic subchondral bone is present.

In the hindfoot, fusion surgery may be performed on one or more of the three joints of this part of the foot (i.e., the talocalcaneal, talonavicular, and calcaneocuboid joints). If only one of these joints is diseased, an isolated fusion of this joint is acceptable.[25] This reduces surgical morbidity and the extent of the procedure. Nevertheless, with fusion of just one of the joints of the hindfoot, motion in the other joints

is reduced.[26] If more than one joint is diseased, a "double" or "triple" arthrodesis is necessary.

In the midfoot, fusion surgery results in negligible loss of motion because the joints of the midfoot normally have less than 10 degrees of motion. In a patient with both OA and inflammatory arthritis, symptomatology is most often limited to the medial (first through third) TMT joints. The lateral (fourth and fifth) TMT joints are infrequently symptomatic, even in the setting of advanced radiographic changes.

Finally, in the forefoot, fusion surgery is indicated only for the first MTP joint. This procedure is used for both arthrosis and advanced hallux valgus (bunion) deformities. When the first MTP joint is fused, it is positioned in a slightly dorsiflexed position to assist ambulation. With MTP fusion in 47 patient feet, Coughlin[27] reported 96% good to excellent results and 100% fusion at an average 6.2-year follow-up.

In summary, fusion surgery generally provides reliable pain relief and a stable, plantigrade foot. Nevertheless, the loss of motion of the fused joint can lead to increased motion and altered biomechanics at adjacent joints. This result ultimately may lead to arthritic changes in these joints.[28] Further, fusion surgery may lead to subtle, albeit real, changes in gait.[29] Finally, the minimal ramifications of fusing just one joint may become much greater in the setting of a subsequent fusion in either the ipsilateral or contralateral limb.

## Arthroplasty

Concerns regarding fusion have driven many to work toward improving joint replacement surgery (arthroplasty) in the foot and ankle. Most notably, total ankle replacement surgery has evolved and is now a viable alternative to arthrodesis. Nevertheless, although there are many orthopedic surgeons who perform ankle replacement surgery, there are still some who do not or who do so on a limited basis. The U.S. Food and Drug Administration currently approves five ankle prostheses for implantation. Robust long-term survival data as published for hip and knee arthroplasty are not yet available.

The main advantage of ankle arthroplasty is preservation of motion. Its main two disadvantages are technical complexity and the difficulty with subsequent fusion if the procedure fails. In general, ankle replacement surgery is indicated for middle-aged and elderly individuals with low functional demands and minimal deformity. Two other indications especially pertinent in patients with ankle arthritis include (1) bilateral disease and (2) concomitant ipsilateral hindfoot disease or pre-existing arthrodesis. The paradox of ankle replacement surgery is that ankle replacement is contraindicated in young patients, for whom preservation of motion is most important. On the other hand, arthroplasty is more commonly performed in older patients, for whom preservation of motion is less important and who might do fine with a fusion. Nevertheless, total ankle replacement surgery continues to evolve, and reported success rates with modern designs continue to improve[30,31] (Figure 49-4).

In the foot, arthroplasty is performed by some surgeons for the first MTP joint. Results from the relevant literature are still somewhat conflicted, however. Although some encouraging early results with arthroplasty were achieved, other studies have shown high rates of implant failure and loosening secondary to synovitis from polymeric silicone (Silastic) particle wear.[32-34] Further, advanced deformity, often present in patients with RA, is considered to be a relative contraindication to first MTP joint arthroplasty. Nevertheless, new implant designs may hold increased promise. In general, these implants are lower profile and resect less bone, which also makes it easier to perform a subsequent fusion, if necessary.

**Figure 49-4** Anteroposterior radiograph of total ankle arthroplasty.

## Osteotomy

Corrective osteotomies are used for two primary reasons in the treatment of RA: to correct deformity, to redistribute forces on a joint or the terminal aspect of a bone, or both.

Examples of osteotomies to correct deformity include calcaneal osteotomies for pes planovalgus and metatarsal osteotomies for hallux valgus. Previously, patients with RA and concomitant pes planovalgus or hallux valgus underwent fusion surgery. However, with advances in medical management of the disease, it is not unreasonable to attempt joint preservation surgery in patients who have mild to moderate disease, healthy soft tissues, and flexible deformities.

Examples of osteotomies to redistribute forces include tibial osteotomies in the setting of eccentric ankle arthritis and metatarsal osteotomies in the setting of metatarsal overload and metatarsalgia. Patients requiring surgery for ankle RA previously underwent fusion surgery only, while patients requiring surgery for metatarsalgia underwent metatarsal head resection. Again, however, advances in medical management of the disease allow joint preservation osteotomies to be considered. This is especially the case for metatarsalgia, which is common in patients with RA, yet increasingly does not entail frank dislocation or articular erosion.

### Ostectomy

Although more commonly seen in patients with OA, some patients with RA may present with symptoms of mechanical ankle impingement arising from anterior bone spurs. In cases without global joint destruction, surgical resection of the spurs, or cheilectomy, is a reasonable treatment. Although no studies have examined cheilectomy in RA specifically, patients with less severe erosive changes tend to be more satisfied with the results of cheilectomy.[35]

### Synovectomy

For those patients with inflammatory arthritis resistant to medical management and nonoperative treatment, synovectomy can provide a period of pain relief for many patients.[36,37] It is thought that early synovectomy of either the affected joint or tendon may help halt the progress of joint destruction. Joint synovectomy is indicated in those who have failed medical management yet still have a relatively preserved articular surface. This may be performed arthroscopically or open through a traditional arthrotomy. Otherwise, synovectomy of the affected tendons allows some preservation of function.

## CONCLUSION

Foot and ankle pain is a prevalent and potentially debilitating problem. Unfortunately, many forms of arthritis, including RA, establish a vicious cycle of foot and ankle pain and altered biomechanics. Synovitis and articular erosions lead to both pain and deformity. A proper history and physical examination are essential for establishing an anatomic diagnosis. Although advanced imaging modalities such as MRI and CT can be useful as adjuncts, radiography remains the gold standard. Nonoperative modalities such as medications, bracing, physical therapy, orthotics, and footwear modification are able to relieve pain and maintain function for many. For recalcitrant symptoms, substantial relief may be afforded by surgical intervention in the form of arthrodesis, arthroplasty, osteotomy, ostectomy, and synovectomy.

CHAPTER 50

# Hand and Wrist Pain

Carrie R. Swigart • Felicity G. Fishman

**KEY POINTS**

- Patients with carpal tunnel syndrome typically present with nocturnal paresthesias associated with intermittent pain or paresthesia during the day.
- Ganglia are mucin-filled cysts arising from joint capsules or tendon sheaths. If they are particularly symptomatic, treatment with corticosteroid injections may be attempted, but surgical excision may be necessary.
- De Quervain's disease—that is, inflammation of the extensor pollicis brevis and abductor pollicis longus tendons in the first dorsal extensor compartment—is common in women and is associated with repetitive hand activities, such as caring for an infant.
- Painful osteoarthritis involving the carpometacarpal joint of the thumb can often be treated successfully with splinting.
- Trigger fingers, caused by thickening of the A1 retinacular pulley in the palm, usually can be treated with corticosteroid injections and splinting.

The multiple functions that the hand performs in daily life are usually taken for granted until the hand becomes affected by disease or injury. Depending on the nature of the disorder, patients have different adaptive capacities. Patients presenting with pain and dysfunction of the hand, wrist, or both represent a wide spectrum, diverse in age, occupations, and avocations. These patients have a broad range of medical conditions that may or may not be related to their current problem. Each patient has a different story to tell about his or her hand and wrist and why he or she is seeking treatment. It is the clinician's role to sort out these various factors, some of which may seem confounding, and determine the most appropriate diagnosis and course of treatment.

This chapter presents guidelines that are useful in the evaluation of patients presenting with hand and wrist pain. Complete coverage of all of the various conditions that can affect the hand and wrist is beyond the scope of this chapter. Instead, the conditions discussed include the most common disorders seen by general practitioners and hand surgeons. The conditions are grouped by their anatomic area to include pain localized to the volar, dorsal, radial, or ulnar wrist; the base of the thumb; and the palm and digits.

## PATIENT EVALUATION

### Anatomy

The complex anatomy of the hand and wrist involves many structures that interact in close proximity to one another. Several different disorders can manifest with similar symptom patterns despite varying diagnoses. A precise knowledge of the anatomy of the hand and wrist often eliminates several diagnostic considerations on the basis of the physical examination alone. The history of the illness and the examination also help narrow further investigation by enabling the physician to better choose appropriate additional diagnostic tests. Several common sites of pain in the hand and wrist and their corresponding leading diagnoses are illustrated in Figure 50-1. Pain in one location can have multiple causes depending on the patient profile and the history of the problem. A thorough review of the pertinent regional anatomy is important to help differentiate the many possible causes of hand and wrist pain.

### History

Important patient factors include age, sex, hand dominance, occupation, and hobbies or sports. When determining the history of the problem, a history of recent or distant trauma should be sought, and an estimation of the severity of the trauma should be noted. Next, questions about the duration and frequency of the pain and its intensity and quality should be addressed. The pain of degenerative arthritis is often described as a localized "toothache"-type pain that is always present at a low level and increases with activity, whereas the pain of tendinitis may be sharp, poorly localized, and present only with activity. Rheumatoid arthritis (RA) manifests initially with hand and wrist involvement in 25% of patients and is characterized by joint effusion, with bilateral hand and wrist involvement and morning stiffness. Nighttime symptoms of a burning-type pain in the hand and wrist that are exacerbated by arm position are often associated with nerve entrapment syndromes. Specific activities that either cause pain or alleviate it should also be noted. Arthritis at the base of the thumb, or first carpometacarpal joint, is often aggravated by opening jars, turning doorknobs, and doing needlework or other hobbies.

## PHYSICAL EXAMINATION

A thorough examination of the involved extremity and comparison with the uninvolved extremity are essential.

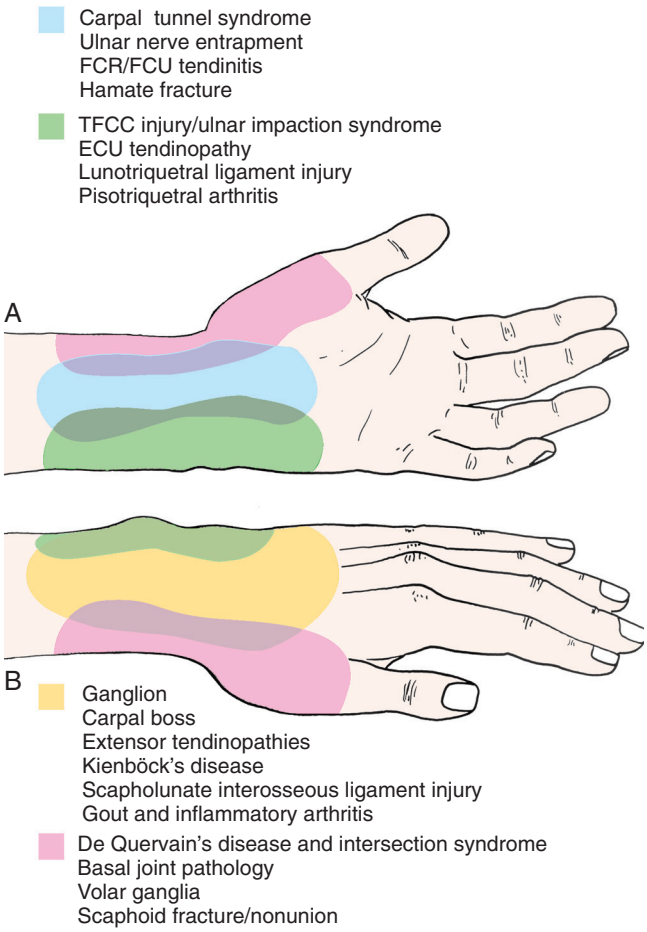

**Figure 50-1** **A,** Palmar and ulnar view of the hand and wrist with areas of pain and tenderness marked with their corresponding leading differential diagnoses. **B,** Dorsal and radial view of the hand and wrist with areas of pain and tenderness marked with their corresponding leading differential diagnoses. ECU, Extensor carpi ulnaris; FCR, flexor carpi radialis; FCU, flexor carpi ulnaris; TFCC, triangular fibrocartilage complex.

Attention should be directed to abnormalities of the more proximal joints of the elbow and shoulder and the cervical spine. As the differential diagnosis narrows, the examination should be tailored as needed to include or eliminate any possible systemic causes. As with other musculoskeletal examinations, the range of motion of the involved joints should be observed and compared with the opposite side. Any difference between active and passive motion should be noted. Careful palpation for the site of maximal tenderness is important in differentiating the source of the pain and is particularly important when trying to exclude possible factors of secondary gain. Measurements of grip and pinch strength are also helpful in many situations as a diagnostic aid and a baseline measurement to follow for improvement. Many provocative maneuvers are useful in differentiating causes of pain; these maneuvers are discussed with the specific disease with which they are associated.

## Imaging Studies

Technologic advances have increased the availability of imaging studies for the hand and wrist. Improvements in MRI resolution using small joint coils allow more precise imaging of small structures in the hand and wrist. Advancements in ultrasound technology have allowed this tool to be increasingly used in the diagnosis of musculoskeletal complaints. With the multitude of ancillary studies available, it is important to be selective in using these tools to establish or refute diagnostic possibilities. With cost containment in mind, imaging studies should be used most often to confirm a diagnosis rather than to find one. An understanding of the advantages and limitations of each tool is necessary to enable them to be used to their fullest potential.

Among the available tools, plain radiographs are the easiest to perform and most readily available. A routine hand or wrist series, including anteroposterior, lateral, and oblique views, is a useful screening tool but often lacks the required specificity. Depending on the suspected diagnosis, many special views are available. These views are discussed later in this chapter with the specific diagnoses to which they pertain.

When further detail of the bony anatomy is required, CT is currently the best available tool. The most common uses for CT in the hand and wrist include evaluation of intra-articular fractures of the distal radius and metacarpals, scaphoid fractures and nonunions, and intraosseous cysts or tumors.[1,2]

Advances in ultrasound and MRI technology have enhanced our ability to evaluate the soft tissue structures of the hand and wrist. Smaller ultrasound probes with higher resolution have made it possible to visualize and differentiate structures such as flexor tendons, ganglion cysts, and ligaments. MRI technology is constantly improving, providing new uses in the hand and wrist. By altering the parameters of this test, information about anatomy and physiology can be obtained.[3] Specific uses of these tests and others such as arthrography, ultrasound, and bone scans are addressed with the diagnoses for which they are most useful.

## Additional Diagnostic Tests

### Neurodiagnostic Tests

Neurodiagnostic tests, including nerve conduction studies and electromyography, are useful in the diagnosis of suspected neurologic disorders of the upper extremity. Specifying the type and nature of the examination required enhances the information gained by these studies. If a nerve compression syndrome such as carpal or cubital tunnel syndrome is suspected, nerve conduction studies may be sufficient without the added cost and patient discomfort of formal electromyographic testing. Nerve conduction studies evaluate the speed of conduction of motor and sensory nerves across a set distance at a specific location and compare this speed with established normal values. A decrease in the speed of nerve conduction, as evidenced by an increase in the latency, is seen with localized nerve compression and is shown in several different nerves concomitantly in demyelinating diseases such as multiple sclerosis. When more severe nerve injuries are suspected or if there is clinical evidence of muscle weakness or atrophy, an electromyogram can be useful to evaluate the extent of the process or rule out a myopathic process.[4]

### Injections and Aspirations

The use of injections and aspirations can be therapeutic and diagnostic. Corticosteroids can be administered selectively in conjunction with a local anesthetic for more lasting relief and in some cases can be curative.[5-11] Some of the most common sites for injection are the A1 pulley region of the finger for trigger finger, the carpal canal for carpal tunnel syndrome, and the first dorsal compartment of the wrist for de Quervain's disease.

Aspiration of joints or other fluid collections, such as ganglia, can yield vital diagnostic information and can be therapeutic. If infection is suspected, aspiration should be used to obtain a sample of joint fluid for gram stain, cell count, and culture. Diagnoses such as gout and pseudogout can be confirmed by crystal analysis under polarized light. Many ganglia and retinacular cysts can be treated temporarily or permanently with simple aspiration.[12,13]

The accuracy of injections and aspirations can be increased with the use of ultrasound. This modality can aid in the injection of symptomatic trigger fingers, de Quervain's tenosynovitis, and carpal tunnel syndrome. Ultrasound-guided injections were found to be in the tendon sheath 70% of the time versus 15% of the time when ultrasound was not used.[13a,13b] Joint injections or aspirations, as well as aspiration of ganglia, also can be greatly aided by ultrasound guidance.[13c]

### Arthroscopy

Direct visualization of a joint via arthroscopy can be an invaluable diagnostic tool. Despite the increasing sensitivity of imaging techniques such as MRI, arthroscopy provides a dynamic evaluation that static imaging cannot provide.[14] Since the first published report of a series of cases by Roth and colleagues in 1988,[15] it has become the "gold standard" for evaluation of chronic wrist pain.[16-18] With new surgical techniques being developed, surgeons often can proceed directly to the definitive treatment using arthroscopy entirely or in part.[19-24]

## COMMON CAUSES OF HAND AND WRIST PAIN

## Wrist Pain: Palmar

### Carpal Tunnel Syndrome

Carpal tunnel syndrome (CTS) is the most commonly diagnosed compression neuropathy in the upper extremity. It usually occurs as an isolated phenomenon, but symptoms of CTS can accompany many systemic diseases, such as congestive heart failure, multiple myeloma, and tuberculosis.[25-28] More commonly, CTS is associated with conditions such as pregnancy, diabetes, obesity, RA, and gout.[29-39]

The classic constellation of symptoms consists of nocturnal paresthesias in the affected digits; paresthesias or hypoesthesias in the thumb, index, and long fingers; and weakness or clumsiness of the hand. Patients often report forearm and elbow pain that is aggravated by activities but is poorly localized and aching in nature. Occasionally, more proximal symptoms such as shoulder pain are the main presenting complaint.[40] Past reports have indicated a 3:1 prevalence of CTS in women. Approximately half of patients are aged 40 to 60 years, although occasionally CTS has been diagnosed in children.[41,42]

The diagnosis of CTS is usually clinical. Tinel's sign, shown by radiating paresthesias in the median nerve distribution with gentle percussion over the volar wrist, indicates nerve irritation. Reproduction of symptoms with wrist flexion, as described by Phalen,[43] and with the carpal compression test, as described by Durkan,[44] has been shown to be more specific.[45] Decreased sensibility and thenar atrophy are late signs seen in persons with advanced median nerve entrapment. Bilateral electrodiagnostic tests, specifically nerve conduction velocity testing, should be used to confirm the diagnosis, particularly in patients claiming a compensable injury or in patients with atypical signs or symptoms. Prolonged motor and sensory latencies across the carpal canal confirm pathologic compression of the median nerve.[46-48] In patients with classic clinical findings, a study found that CTS could be diagnosed with a high degree of accuracy on clinical grounds alone and that the addition of electrodiagnostic tests did not increase the accuracy.[49] When attempting to differentiate CTS from more proximal nerve entrapments such as cervical root compression or thoracic outlet syndrome, the addition of electromyography of the cervical paraspinal muscles and proximal conduction tests (H reflex, f waves) can be useful.[50]

Conservative treatment for CTS consists of splinting of the wrist in a neutral position and consideration of oral nonsteroidal anti-inflammatory drugs (NSAIDs) for pain control. Splinting should be used sparingly during the workday to prevent secondary muscle weakness and fatigue and is best prescribed to prevent provocative wrist positioning at night. The splint should not hold the wrist in extension beyond 10 degrees (Figure 50-2). "Off the shelf" splints often need to be manipulated to neutral or 10 degrees of extension before being provided to the patient. Although splinting may be beneficial for relief of symptoms in cases of mild compression, its long-term effectiveness is limited.[51] The use of vitamin $B_6$ (100 to 200 mg/day) has been helpful in some cases, but its efficacy has not been confirmed in a randomized trial. The popularity of corticosteroid injections in the treatment of CTS has waxed and waned during the past half century. Although it has been shown to be quite

**Figure 50-2** Typical night splint used in the treatment of carpal tunnel syndrome.

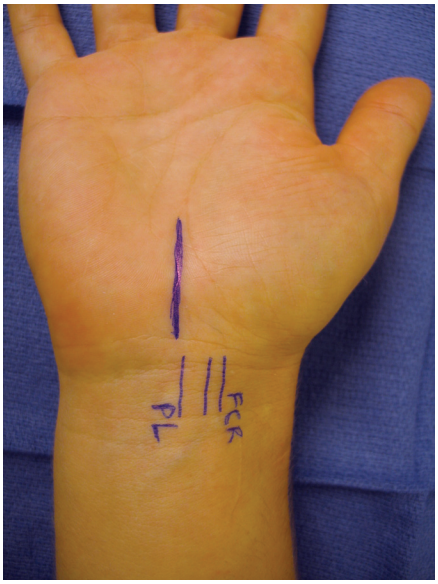

**Figure 50-3** Usual incision used for release of the carpal tunnel. Note its position just ulnar to the course of the palmaris longus tendon (PL) and the relative position of the flexor carpi radialis tendon (FCR).

effective in the short term, the long-term efficacy is mixed.[52-54] In addition, injections have been associated with exacerbation of the condition and permanent median nerve injury if performed incorrectly.[55,56] For these reasons, injections are most often indicated in cases when the condition is thought to be temporary, such as with pregnancy, or if surgery must be deferred because of a medical condition or major life event.

Surgical release is indicated for patients with confirmed CTS who have not responded to a course of conservative treatment. In patients who exhibit late findings of objective sensory loss or thenar atrophy, early surgery should be recommended. The incision for a modern carpal tunnel release is not more than 3 cm long and parallels the skin creases of the palm (Figure 50-3).

### Ulnar Nerve Entrapment: Cubital Tunnel Syndrome

Entrapment of the ulnar nerve as it passes through the cubital tunnel just posterior to the medial epicondyle of the elbow can manifest with symptoms localized to the ulnar border of the hand. Medial forearm pain and irritability of the ulnar nerve at the elbow may be present as well. Presenting symptoms usually consist of paresthesias, numbness, or both in the small and ring fingers. Percussion of the nerve in the cubital tunnel elicits Tinel's sign. Prolonged elbow flexion reproduces the symptoms. In contrast to CTS, it is not unusual for patients to present with early atrophy of the intrinsics, which is most easily appreciated in the first dorsal interosseous muscle.

Electrodiagnostic studies can help confirm the diagnosis and differentiate cubital tunnel syndrome from more distal compression of the ulnar nerve in Guyon's canal (discussed later). If malalignment of the elbow is present or the patient relates a history of childhood trauma, radiographs should be obtained to rule out a supracondylar or epicondylar malunion. So-called tardy ulnar nerve palsy can develop years after a supracondylar fracture of the elbow.[57]

Conservative treatment includes strategies to help the patient avoid having the elbow flexed for prolonged periods, particularly at night. Soft or semirigid elbow splints prevent elbow flexion beyond 50 to 70 degrees. NSAIDs can be beneficial in acute or traumatic cases. Surgical decompression of the nerve is indicated when a person does not obtain relief from splinting and activity modification or when clinical or electrodiagnostic evidence of muscle denervation is present.

### Ulnar Nerve Entrapment: Guyon's Canal

In 1861 Guyon[58] published a description of the contents of an anatomic canal at the wrist. The distal branches of the ulnar nerve and the ulnar artery pass through this space. As it exits the canal, the ulnar nerve divides into its sensory and motor branches. Compression of the nerve within or proximal to the canal usually manifests with a combination of sensory and motor symptoms in the ulnar nerve distribution. Patients report numbness and paresthesias of the palmar aspect of the ring and small fingers. Motor symptoms are usually described as a cramping weakness with grasping and pinching. As with median neuropathy, atrophy of the intrinsics and objective sensory loss are late findings.

In contrast to carpal tunnel syndrome, in which patients usually have an ill-defined onset of symptoms, ulnar nerve compression in the canal of Guyon is often of more acute onset. It can be associated with repeated blunt trauma,[59-61] a fracture of the hamate or the metacarpal bases, or occasionally a fracture of the distal radius.[62,63] Space-occupying lesions such as a ganglion, lipoma, or anomalous muscle also can cause compression.[64-68] Because of the difference in etiology, this nerve entrapment syndrome often is not amenable to conservative treatment. If an anatomic lesion such as a fracture or a mass is present, it must be addressed. If repetitive blunt trauma is the cause, without associated fracture or arterial thrombosis, splinting and activity modification can alleviate the symptoms.

### Flexor Carpi Radialis and Flexor Carpi Ulnaris Tendinitis

Similar to other tendinopathies around the wrist, irritation of the wrist flexors occurs with stress of the wrist in a particular position. Activities that require forced wrist flexion for prolonged periods or with repetition put patients at risk for inflammation around the flexor carpi radialis tendon,[69] the flexor carpi ulnaris tendon, or both. The condition manifests with tenderness along the course of the tendon, especially near its insertion. Wrist flexion against resistance with radial or ulnar deviation reproduces the symptoms. Treatment consists of splinting and rest, elimination of activities that cause pain, and use of oral NSAIDs. Injection of a corticosteroid into the flexor carpi radialis or flexor carpi ulnaris sheath may be curative. Sharp pain that is associated with an intense inflammatory localized reaction is suggestive of calcific tendinitis and is most commonly seen around the flexor carpi ulnaris tendon.[70,71] If calcific tendinitis is suspected, a plain radiograph can be useful in confirming the diagnosis, but the calcification may not

become apparent until 7 to 10 days after the onset of symptoms.

### Hamate Fracture

An uncommon and underdiagnosed cause of palmar pain in young, active persons is a fracture of the hook of the hamate. These fractures can occur from a fall on an extended wrist, from a "dubbed" golf shot, or from forcefully striking a ball with a club or bat. Plain radiographs of the wrist are usually read as normal. Pain in the base of the palm overlying the hamate is the most common presenting symptom. Often the pain is present only with the activity that caused the fracture. Because of the proximity of the ulnar nerve, patients also can have sensory and motor symptoms of distal ulnar neuropathy. Occasionally, in the acute setting, vascular complaints such as cold intolerance or frank ischemia from ulnar artery thrombosis can be the presenting condition. Fracture of the hamate hook has also been reported to cause rupture of flexor tendons if left untreated.[72]

A carpal tunnel radiographic view, obtained with the wrist in a hyperextended position, may show the fracture (Figure 50-4A). Alternatively, a selective CT scan through the hamate is a more accurate way to confirm the diagnosis (Figure 50-4B).[73] If diagnosed within 2 to 3 weeks of injury, casting should be attempted to allow the fracture to heal.[74] If casting fails to achieve healing or if the fracture is diagnosed late, surgical treatment is indicated; most authors favor excision of the hook, followed by a gradual return to activities.[75-78]

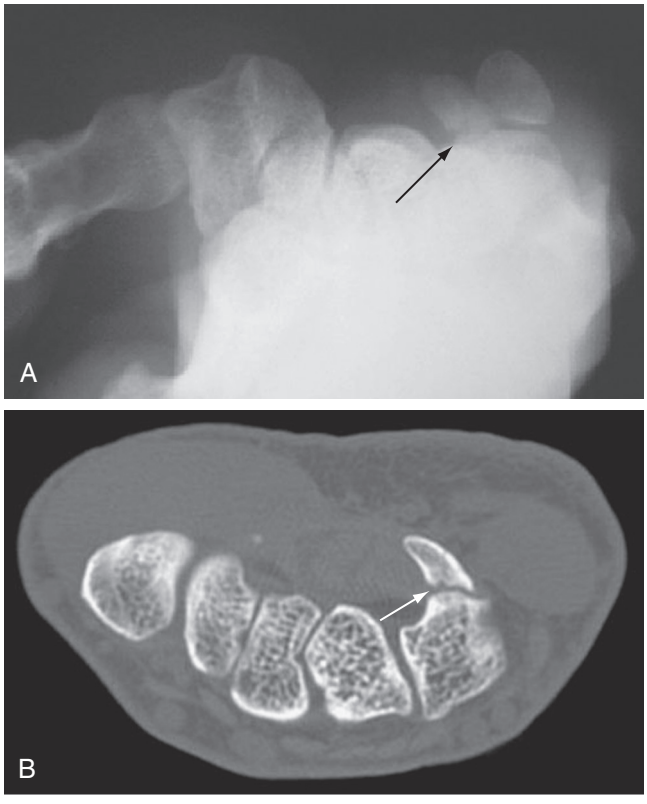

**Figure 50-4** **A,** Carpal tunnel view radiograph showing a hamate hook fracture *(arrow)*. **B,** Coronal computed tomography scan showing the same hamate hook fracture *(arrow)*.

## Wrist Pain: Dorsal

### Ganglion

Ganglia account for 50% to 70% of all soft tissue tumors of the hand and wrist. Of these, 60% to 70% occur around the dorsal wrist. These mucin-filled cysts usually arise from an adjacent joint capsule or tendon sheath. The most common site of origin in the wrist is the scapholunate ligament. Although most ganglia occur as a well-circumscribed and obvious soft mass, some are evident only with the wrist in marked volar flexion. As a result of their characteristic appearance, ganglia usually are not misdiagnosed but should be differentiated from the less well-demarcated swelling of extensor tenosynovitis, lipomas, and other hand tumors. Plain radiographs are typically normal but occasionally show an intraosseous cyst or an osteoarthritic joint. Some ganglia may not be clinically apparent and are known as "occult" ganglia. Ultrasound and MRI have been shown to be useful in the diagnosis of these ganglia.[79,80]

Not all ganglia are painful. Patients may present with reports of wrist weakness or simply because of the cosmetic appearance of the cyst. In approximately 10% of cases, evidence of associated trauma to the wrist is seen. The ganglia may appear suddenly or develop over many months. Intermittent complete resorption followed by reappearance months or years later is common.

Most conservative measures such as splinting and rest have only a temporary effect on ganglia. They tend to diminish in size with rest and enlarge with increased activity. Spontaneous rupture is common, and, at one time, attempting to rupture the cyst with a heavy object, such as a large book, was recommended as treatment. Aspiration can be performed but has mixed results because of the thick gelatinous nature of the fluid within the cyst. Even if adequate decompression of the cyst can be achieved, reaccumulation of the fluid usually occurs. Aspiration in conjunction with irrigation or injection of corticosteroids can be effective in alleviating the symptoms for varying periods.[12,13,81]

Occasionally a ganglion can interfere with the function of the wrist by limiting motion, especially in extension. Pressure of the mass on the terminal branches of the posterior interosseous nerve may be painful. Excision is generally curative but may result in short-term stiffness and some loss of terminal flexion as a result of surgical scarring. Occasionally a patient desires excision of the cyst for cosmetic reasons. With proper excision, recurrence is less than 10%,[82-84] but when the dissection is incomplete and fails to identify the origin of the cyst, recurrence rates can reach 50%. Arthroscopic resection has been shown to be a safe and effective method of treating dorsal wrist ganglia.[23,24]

### Carpal Boss

Often confused with a dorsal ganglion, the carpal boss is a bony, nonmobile prominence on the dorsum of the wrist. It is an osteoarthritic spur that forms at the second or third carpometacarpal joints.[85] The boss is most evident with the wrist in volar flexion. The vast majority are asymptomatic, but some persons may present with pain and localized tenderness over the prominence. The condition is twice as common in women as in men, and most patients are in their

20s to 30s. Radiographs are best taken with the hand and wrist in 30 to 40 degrees of supination and 20 to 30 degrees of ulnar deviation to put the bony prominence on profile (the "carpal boss view").[86] Conservative treatment consists of rest, immobilization, NSAIDs, and occasionally injection with corticosteroids. If persistently painful despite these measures, surgical excision of the boss may be necessary but is associated with a prolonged recovery and continued symptoms in a high percentage of patients.

### Extensor Tendinopathies

The extensor pollicis longus (EPL) tendon can be irritated as it passes around Lister's tubercle. In contrast to other tendinopathies around the wrist, this condition carries a significant risk of tendon rupture. Early diagnosis and sometimes urgent operative treatment are necessary to prevent this complication. Localized pain, swelling, and tenderness are the hallmarks of this condition, and similar to other tendinopathies, initial treatment consists of decreased activity and splinting. A short course of oral anti-inflammatory medication can be useful in decreasing symptoms. Diagnostic injections with lidocaine can help differentiate the condition from other causes of wrist pain, but corticosteroid injections are not routinely used in this condition because of a propensity for the EPL to rupture in chronic cases.

Patients may present with a rupture of the EPL without antecedent pain or swelling. It is well-known that EPL rupture is associated with fractures of the distal radius that likely occur as a result of a relative "watershed zone" of vascular supply within its tight retinacular sheath as it passes around Lister's tubercle of the distal radius. Tendon rupture most often occurs with minimally displaced or non-displaced fractures and can occur several weeks or months after the original injury.[87-90] Persons with RA and systemic lupus erythematosus are especially prone to rupture of the EPL and other tendons.

### Kienböck's Disease

Kienböck's disease is named for Dr. Robert Kienböck,[91] who in 1910 first described what he postulated were avascular changes in the lunate. Nearly a century later, the cause of this disease remains unclear; it is likely multifactorial. Kienböck's disease should be suspected when a young adult presents with pain and stiffness of the wrist and swelling and tenderness around the region of the dorsal lunate. An increased propensity of the disease occurs among patients with an ulna that is anatomically shorter than the radius (so-called ulnar negative variance). Radiographs are needed to confirm and stage the process. Kienböck's disease is staged by the degree of fragmentation and collapse of the lunate, associated osteoarthritis, and carpal collapse in a system originally proposed by Stahl.[92] In this system, the earliest sign of the disease is a linear or compression fracture in the lunate. Later stages show sclerosis of the lunate, followed by lunate collapse and a loss of carpal height. In the final stage, the carpus shows signs of diffuse osteoarthritis with complete collapse and fragmentation of the lunate (Figure 50-5). With the increased sensitivity of MRI, it is possible to identify avascular changes within the lunate before they become evident on plain radiographs. These avascular changes are referred to as "stage zero" Kienböck's disease.

The treatment for Kienböck's disease is largely surgical. Based on the stage of the disease and the postulated cause, several surgical procedures have been described. In early stages of the disease, when lunate collapse is minimal and no osteoarthritis is present, the goal of surgery is to "unload" the lunate by redistributing articular contact forces and allowing it to revascularize.[93-96] The most common procedure is a radial shortening osteotomy that is performed to neutralize the ulnar variance. In later stages, various intercarpal arthrodeses have been used to readjust and maintain carpal height and alignment.[97-99] More recently, microsurgical techniques have been used to revascularize the lunate with promising early results.[100]

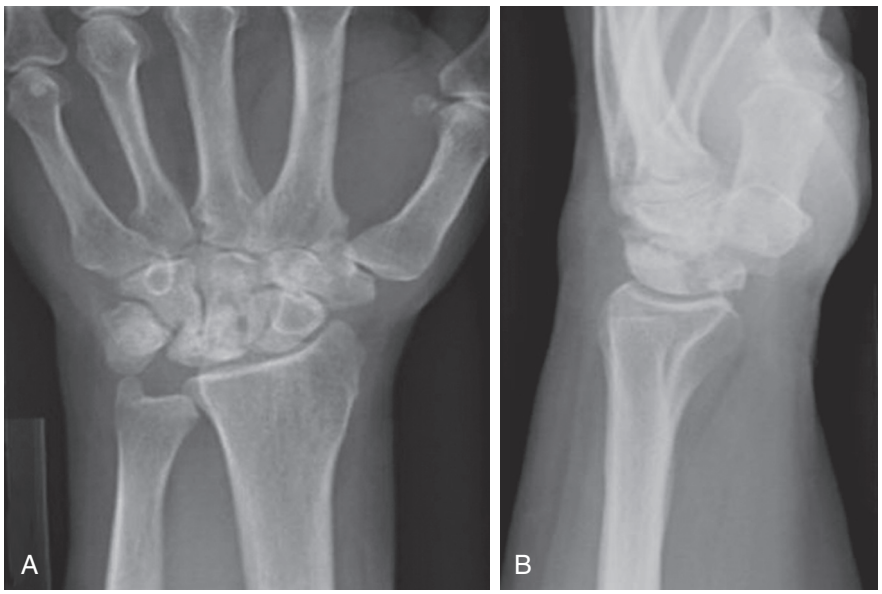

**Figure 50-5** Advanced Kienböck's disease, showing carpal collapse, intercarpal and radiocarpal arthrosis, and fragmentation of the lunate. **A,** Posteroanterior view. **B,** Lateral view.

### Scapholunate Interosseous Ligament Injury

The interosseous ligament between the scaphoid and the lunate is a stout structure, especially dorsally, and usually requires a significant force to cause disruption. The typical mechanism of injury is a fall onto the outstretched hand with the wrist extended. Early diagnosis is essential to prevent the late sequelae of carpal collapse. The key radiographic features of scapholunate dissociation (scapholunate interval widening) are shown in Figure 50-6. The anteroposterior view shows the scapholunate interval better than the posteroanterior view.[101] Early surgical intervention is recommended with the goals of maintaining carpal alignment and preventing an otherwise inevitable progression to carpal collapse and degenerative arthritis.

### Gout and Inflammatory Arthritis

All of the inflammatory arthritides, including the crystal arthropathies, can manifest as dorsal wrist pain. Approximately 25% of patients with a diagnosis of RA present initially with hand and wrist symptoms. The reader is referred to Chapters 94 to 96 for further details.

## Wrist Pain: Ulnar

### Triangular Fibrocartilage Complex Injury and Ulnocarpal Impaction Syndrome

One of the most complex and confusing areas of the wrist from a diagnostic standpoint is the articulation of the ulna with the carpus. The triangular fibrocartilage complex (TFCC), so named by Palmer and Werner,[102] comprises the articular disk itself and the immediately surrounding ulnocarpal ligaments. It can be injured by a variety of acute and chronic mechanisms. Hyperpronation and hypersupination of the carpus during forceful activities are the usual causes of acute injuries, whereas repetitive pronation and supination more often cause attritional changes in the TFCC.

The radius and ulna must remain congruent through a 190-degree arc.[103] Limitation of motion and pain with pronation and supination are consistent with a tear of the supporting ligaments and resultant distal radioulnar joint (DRUJ) instability. If a sufficient portion of the stability has been lost, the ulna appears clinically dislocated or subluxated, and forearm rotation is severely limited. Lateral radiographs of the wrist in neutral and full pronation and supination generally are not specific enough to confirm ulnar subluxation. To evaluate better the congruency of the DRUJ through its range of motion and to assess for subtle subluxations, CT can be performed on both wrists simultaneously in positions of neutral, full pronation, and full supination.[104-107]

Tears of the TFCC may manifest with painful clicking during wrist rotation. Patients generally have localized tenderness on the midaxial border of the wrist and directly beneath the extensor carpi ulnaris tendon. If forced ulnar deviation of the wrist or gripping or both reproduce the patient's symptoms, a degenerative tear of the central portion of the TFCC is more likely. The degenerative tear is frequently a component of the ulnocarpal impaction syndrome, a condition associated with higher than normal loads on the ulnar carpus secondary to a congenitally positive ulnar variance.

Plain radiographs are most useful in determining ulnar variance and for ruling out fractures or arthritis as a cause of ulnar wrist pain. Because of the variable relationship of the radius and ulna depending on forearm rotation, it is important to take standardized films when measuring ulnar variance.[108,109] A posteroanterior view of the wrist with the shoulder abducted to 90 degrees and the elbow flexed to 90 degrees shows the DRUJ in neutral forearm rotation and is easily reproducible (Figure 50-7). Because the ulna lengthens relative to the radius during power grip, a radiograph in

**Figure 50-6** Anteroposterior radiograph of the wrist showing scapholunate interosseous space widening *(arrow)* and scaphoid foreshortening associated with scapholunate interosseous ligament disruption.

**Figure 50-7** Posteroanterior radiograph of the wrist in neutral forearm rotation showing the method of measuring ulnar variance by drawing tangential lines to the distal ulna and distal radius. The space between these lines in millimeters is the ulnar variance. A positive value indicates that the ulnar length is greater than the radial length.

the same position during maximal grip best shows impaction of the ulna on the carpus.

Ancillary studies for TFCC tears include three-compartmental arthrography and MRI. In arthrography, sequential injections of radiopaque dye are performed into the carpal joint, midcarpal joint, and DRUJ. The test is considered positive when the dye is seen leaking from one compartment to another. The site of the leak determines the location of the torn structure.[110] However, several studies have shown that age-related attritional tears occur in the TFCC and other ligamentous structures of the wrist.[111-113] Technologic advancements in MRI have improved the ability to visualize and diagnose abnormalities in the TFCC. MRI can be combined with arthrography to better visualize the TFCC and the intrinsic wrist ligaments. Peripheral detachments and central degenerative tears of the TFCC can be visualized. MRI remains highly operator dependent and technique dependent, and the studies should be interpreted in the context of the findings on physical examination.[114]

Patients presenting with pain localized to the ulnar side of the wrist often respond to simple splinting and rest. This conservative treatment and NSAIDs can be used effectively while a workup is in progress. A course of rest and splinting, followed by a gradual return to activities, may completely alleviate ulnar-sided symptoms.

Despite the advancements in imaging techniques, there is often no substitute for direct visualization of the ulnocarpal joint, DRUJ, or both. Arthroscopy has become an invaluable diagnostic and surgical tool. Tears of the TFCC can be visualized and their clinical significance better determined. Arthroscopy, performed in conjunction with fluoroscopy, can assess for instability of the DRUJ, intercarpal joints, or both. Several surgical procedures can now be performed entirely or in part through the arthroscope.[115,116]

### Extensor Carpi Ulnaris Tendinitis and Subluxation

The extensor carpi ulnaris tendon can become irritated with forced pronation/supination activities, such as putting topspin on a tennis ball. In severe cases the tendon can become unstable around the ulnar head as its restraining dorsal retinaculum becomes increasingly lax. Patients report pain with forceful rotation of the forearm, and sometimes an associated snapping of the extensor carpi ulnaris (ECU) tendon is present. Early treatment consists of immobilization of the wrist and forearm to prevent rotation. Anti-inflammatory oral medication or a cortisone injection can help decrease the inflammation more quickly. After an adequate period of rest, if the acute inflammation resolves but the ECU tendon continues to be unstable, surgery may be indicated to reconstruct or release the sheath at the wrist.

### Pisotriquetral Arthritis

Degenerative changes in the pisotriquetral articulation are usually post-traumatic in nature. Patients may recall a fall onto the extended wrist with direct trauma to the ulnar side of the palm. Affected persons present with pain during passive wrist hyperextension and exacerbation with flexion against resistance. Tenderness and often crepitus occurs with palpation of the pisotriquetral joint. As with many joints, splinting, NSAIDs, and occasionally injection with corticosteroid and lidocaine are the mainstays of conservative treatment. If this approach is inadequate to control the symptoms, surgical resection of the pisiform is indicated.

## Wrist Pain: Radial and Thumb

### De Quervain's Disease and Intersection Syndrome

One of the most common sites of tendon irritation around the wrist is in the first dorsal extensor compartment, a phenomenon known as de Quervain's disease. The tendons involved are the extensor pollicis brevis (EPB) and the abductor pollicis longus (APL). At the level of the radial styloid, these two tendons pass through an osteoligamentous tunnel composed of a shallow groove in the radius and an overlying ligament. Anatomic studies have shown that a high percentage of patients have a divided first dorsal compartment, with separate compartments for the EPB and APL slips, and this feature can account for failure of conservative treatment and injections.[117-119]

Persons with de Quervain's disease are typically women in their 30s and 40s, although the condition can develop in men and women at any age. De Quervain's disease is the most common tendinopathy to develop in postpartum women because of the specific hand and wrist position requirements in the care of an infant. Any activity requiring repeated thumb abduction and extension in combination with wrist radial and ulnar deviation can aggravate this problem. Patients report pain along the course of these tendons with grasping activities. Clinically, tenderness is present along the affected compartment, and swelling may be present over the radial styloid. In severe cases, a creaking sound can be elicited with movement of the involved tendons. Finkelstein's test of forced ulnar deviation of the wrist with the thumb clasped in the fisted palm is pathognomonic of the condition.[120,121]

A less common condition that may occur in the same general location in the wrist is intersection syndrome. Although initially attributed to friction between the first and second dorsal compartment tendons, Grundberg and Reagan[122] subsequently showed that the condition represented a tendinopathy of the radial wrist extensors within the second dorsal compartment.

The primary treatment for de Quervain's disease and intersection syndrome is rest with splinting. For de Quervain's disease, the wrist should be held in slight extension and the thumb abducted in a thumb spica splint to the level of the interphalangeal joint. Immobilization of the wrist alone, in approximately 15 degrees of extension, is usually adequate for intersection syndrome. The addition of a 2- to 4-week course of anti-inflammatory medication also can be helpful. Phonophoresis with a cortisone cream and injection of the compartment with cortisone are second-line treatments if immobilization alone fails to provide adequate relief. Injection of corticosteroid into the affected first dorsal compartment is curative for de Quervain's disease in approximately 75% of patients.[123] Surgery may be indicated for patients who do not respond to a course of conservative treatment, including injection. For de Quervain's disease and intersection syndrome, surgery consists of releasing the stenotic retinacular sheath of the involved compartment.

### Basal Joint Arthropathy

Inflammation and pain related to the carpometacarpal joint of the thumb are common and can occur at any age. In younger patients, instability secondary to ligamentous laxity is associated with joint subluxation and abnormal cartilage wear and may lead to pain with mechanical activities. In women older than 45 years, studies show that 25% have radiographic evidence of degeneration of the basal joint.[124,125] Patients generally present with pain at the base of the thumb that is worsened by pinch activities. They often report difficulty with tasks such as opening jars and bottles or turning doorknobs and keys. The thumb carpometacarpal joint may be swollen and subluxed and is generally tender to palpation. The joint should be assessed for the presence of increased laxity by manual subluxation of the base of the metacarpal out of the trapezial "saddle" with radial and volar force. With advanced degenerative disease, crepitus is sometimes appreciated.

Radiographs should be obtained to determine the stage of the disease. The addition of a basal joint posteroanterior stress film, in which the patient presses the tips of the thumbs together firmly with the nail plates facing up, is helpful in assessing joint subluxation (Figure 50-8). The most commonly used staging system, which was developed by Eaton and Glickel,[126] is based on the degree of involvement of the trapeziometacarpal joint and whether the scaphotrapezial joint is involved.[126] Advancing stages show increased subluxation of the basal joint with development of joint space narrowing, osteophytes, and subchondral cysts.

Regardless of the stage of the disease, the first line of treatment is immobilization of the thumb carpometacarpal joint, leaving the interphalangeal joint free. Splinting has been shown to alleviate the symptoms of carpometacarpal joint inflammation in more than 50% of patients.[127] NSAIDs can be a useful adjunct. Injections of a corticosteroid are effective, usually for just a limited time. Although therapy for thenar muscle strengthening has been advocated, especially in early stages, its benefits are minimal, and occasionally it can aggravate the problem.

Many persons are able to manage their symptoms with a combination of splinting, medications, corticosteroid injections, and activity modification. The most effective splints are those that are custom made of a moldable plastic material. They may be hand based as shown in Figure 50-9 or forearm based to immobilize the wrist as well. If these various nonoperative treatments are insufficient, surgery may be indicated. In persons with advanced degenerative changes and those whose symptoms continue to interfere sufficiently with their daily activities, surgery to replace the joint with a prosthetic device or to excise the trapezium and reconstruct the soft tissue supports is indicated.

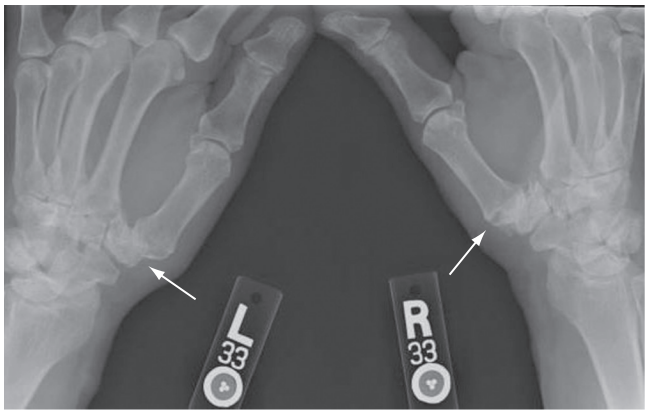

**Figure 50-8** "Basal joint stress" radiograph showing stage 3 degeneration of the left thumb and stage 4 degeneration of the right thumb.

### Thumb Metacarpophalangeal Joint Injuries and Instability

The metacarpophalangeal (MCP) joint of the thumb is primarily stabilized by the radial and ulnar collateral ligaments, which provide radioulnar and dorsal stability.[127a,127b] Ulnar collateral ligament (UCL) injuries result from a sharp radial deviation of the thumb MCP joint, whereas radial collateral ligament (RCL) injuries are generally the product of a sudden adduction of the MCP joint. A complete rupture of the UCL and retraction of the ligament proximal to the adductor aponeurosis is referred to as a "Stener lesion." In this situation, the UCL cannot reapproximate to the anatomic origin of the ligament. Acute UCL injuries are often termed "skier's thumb," whereas chronic attritional ruptures are described as "gamekeeper's thumb." RCL injuries occur less commonly than UCL injuries and are estimated to comprise only 10% to 42% of collateral injuries to the thumb.[127c]

Radiographic evaluation and physical examination remain the mainstays for diagnosis of an RCL or UCL injury. Stress views of the MCP joint can be performed and

**Figure 50-9** Typical hand-based custom-molded splint used in the treatment of symptomatic basal joint arthritis. The thumb interphalangeal joint and wrist are left free to improve the patient's function while wearing the splint.

may demonstrate asymmetry of the joint space. Physical examination, including stress testing of the MCP joint, can determine a partial versus complete tear. Physical examination in the acute setting may be aided by administration of plain lidocaine into the MCP joint to help decrease patient discomfort and anxiety. A 30-degree overall laxity of the affected thumb MCP joint or a 15-degree difference from the contralateral thumb is considered predictive of disruption of the collateral ligament.[127d,127e]

Nonoperative treatment is successful for the majority of acute UCL and RCL tears. Partial tears of the UCL, with a firm endpoint detected on physical examination, can be immobilized for 2 to 6 weeks in a thumb-spica cast or thermoplastic splint and results in a stable, minimally symptomatic joint. Partial or complete tears of the RCL can be similarly treated with immobilization. If gross instability of the MCP joint is present on stress testing with no firm endpoint or if a Stener lesion is suspected, these injuries are best treated with surgical intervention.[127b,127e]

### Volar Ganglion

Another common location for ganglia is the radial side of the volar wrist. Ganglia typically originate from the scaphotrapezial joint but become superficial and are clinically evident at or near the distal wrist crease over the flexor carpi radialis tendon. Volar ganglia can occur in close proximity to the radial artery and should be differentiated from a radial artery aneurysm. Aspiration, if attempted, should be performed carefully to avoid vascular injury, and surgery should be preceded by performance of an Allen test to document patent ulnar arterial flow. Volar ganglia are associated with a higher recurrence rate and a higher complication rate than their dorsal counterparts.[128]

### Scaphoid Fracture with Nonunion

Occasionally a young or middle-aged patient presents with a nonunited scaphoid fracture with no recollection of a traumatic incident. When evaluating a relatively young patient with pain at the base of the thumb, wrist swelling in the region of the anatomic snuffbox, and a decreased range of motion of the wrist, plain radiographs and a specialized ulnar-deviation "navicular" radiograph should be obtained to rule out scaphoid disease. In patients in whom a scaphoid nonunion has been present for a significant period, secondary changes in carpal alignment and joint degeneration have usually occurred. Although treatment with splint or cast immobilization can be attempted, surgical repair of the scaphoid or another wrist salvage procedure is usually required.

### Distal Radius Fractures

Distal radius fractures often occur as a result of a fall on an outstretched hand. Patients with a distal radius fracture generally present with a history of recent trauma with subsequent pain, swelling, ecchymosis, and often an obvious deformity of the affected wrist. The median nerve and carpal tunnel are in close anatomic proximity to the fracture site, and the patient may describe paresthesias in addition to pain. Radiographs of the wrist will demonstrate the degree of displacement and whether the fracture is extra-articular or intra-articular. Although many distal radius fractures can be treated successfully with closed reduction and immobilization (generally performed in the setting of the emergency department or urgent care facility), a fivefold increase in the operative treatment of distal radius fractures in elderly persons from 1996 to 2005 has recently been reported.[128a] The vast majority of distal radius fractures are still treated nonoperatively, but improvements in orthopedic implants have led to an increasing trend toward operative fixation of these injuries.

## Palm

### Trigger Finger

Painful clicking and locking of the digits in flexion is one of the most common causes of pain in the hand. This condition, caused by a thickening of the A1 retinacular pulley in the palm, is commonly known as *trigger finger*. The thumb is the most commonly affected digit, followed by the ring and long fingers.[129] Patients may present with isolated activity-related pain in the proximal interphalangeal joint without frank clicking or locking. Early clicking is felt as a snapping sensation during digital motion and is frequently worse upon awakening. As the condition progresses, the digital range of motion can be reduced and secondary proximal interphalangeal joint contractures develop. The final stage is a locked trigger finger that cannot be straightened actively.

Primary trigger finger is the most common type and is found most often in middle-aged persons. Triggering of the thumb is four times more frequent in women than in men.[5] Secondary triggering is seen in association with such diseases as RA, diabetes, and gout. In this type, trigger fingers are often multiple and can co-exist with other stenosing tendinopathies, such as de Quervain's disease or CTS. Congenital or developmental triggering can be identified in children and is much less common. Similar to its presentation in adults, the thumb is most commonly affected, but in contrast to adults, triggering often presents with the interphalangeal joint locked in flexion.

Nonoperative treatment of this condition consists primarily of splinting and local steroid injections. Splinting is most effective at night to prevent the digit from locking. In adults, injection of steroid into the tendon sheath has been shown to be quite effective (Figure 50-10).[5,6,130] Injection is used infrequently in infants or children. When nonoperative treatments fail to give lasting relief, surgical treatment consists of longitudinal division of the A1 pulley at the level of the metacarpal head, which is a simple procedure that yields reliable results with few complications.

### Retinacular Cysts

Retinacular ganglion cysts can occur in conjunction with a triggering digit or in isolation. These cysts are located at the base of the digit over the A1 pulley as a discrete, firm, pea-sized nodule. They originate from the flexor tendon sheath or annular pulleys and contain synovial fluid. Patients usually report pain when gripping objects or with direct pressure over the cyst. A retinacular cyst is most easily

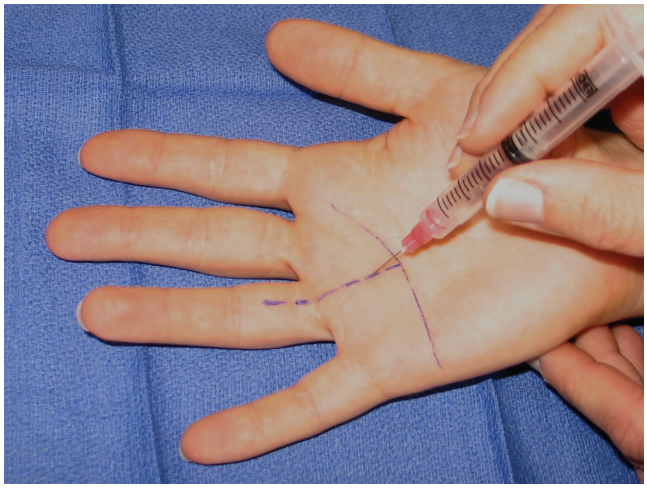

**Figure 50-10** Technique for injecting a trigger finger. The *solid line* denotes the distal palmar crease. The *dashed line* indicates the midline of the digit. The needle enters at an angle of between 45 and 60 degrees.

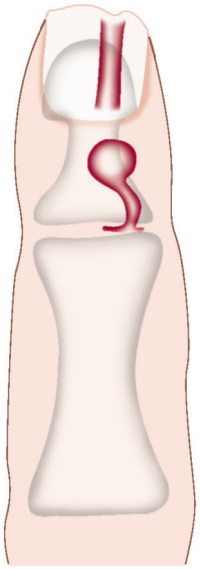

**Figure 50-11** Dorsal view of a digit with an as yet clinically inapparent mucous cyst and the corresponding groove deformity of the nail plate.

treated initially by needle decompression, with care to avoid injury to the sensory nerves that lie immediately adjacent to the flexor tendon and associated cyst. Approximately 50% recur after aspiration, and surgical resection may be required.

## Digits

### Mallet Finger

Mallet finger refers to a loss of terminal extension of the distal interphalangeal joint of the digit and can be classified as bony or soft tissue depending on where the disruption in the extensor mechanism occurred. Mallet fingers can occur with minimal trauma, such as tucking in bed sheets, and may not be recalled by the patient, which sometimes leads to a delay in diagnosis and treatment. When a person presents with a digit that droops at the distal interphalangeal joint and cannot be actively extended but has full passive motion, a radiograph should be obtained to determine if there is an associated fracture of the distal phalanx. An extension splint is the treatment of choice for bony and soft tissue mallet fingers. The distal interphalangeal (DIP) joint should be held in full extension, and care should be taken not to force the DIP joint into hyperextension to prevent dorsal skin ischemia and necrosis. Splinting is performed full time for 6 to 8 weeks. The patient should not remove the splint for showering or any other activity but may change the splint carefully for skin care, provided that the joint is maintained in extension. Proximal interphalangeal flexion exercises are initiated from the outset and are important to help reset the tension in the extensor mechanism. Gentle DIP flexion exercises are begun at 8 weeks, and splinting is decreased to nighttime between 8 and 10 weeks. Patients usually can expect a small extension lag, on the order of 5 degrees, and a return of most of their flexion.

### Osteoarthritis of the Digits

Osteoarthritis of the interphalangeal (IP) joints is extremely common in older persons and is most often manifested as Heberden's nodes of the DIP joint. Despite gross deformities, pain and dysfunction may be minimal. A mucous cyst may appear in association with degenerative arthritis. Mucous cysts appear on the dorsum of the joint and can cause nail growth deformities as a result of pressure on the germinal matrix (Figure 50-11). The changes in nail growth may precede clinical detection of the cyst. These cysts should not be aspirated with a needle because of the close proximity of the DIP joint and the risk of secondary joint infection. Treatment consists of DIP joint immobilization to control symptoms or surgical excision of the cyst and, in particular, the underlying osteophytic spurs.

### Tumors

Benign bone tumors such as simple bone cysts and enchondromas are common in the phalanges. These tumors usually cause no symptoms and frequently are diagnosed as incidental findings on routine hand radiographs. Enchondromas are most commonly located in the metaphysis of the proximal phalanx and may lead to fracture with minimal trauma as a result of weakening of the bone structure. If a pathologic fracture occurs, nonoperative treatment is indicated until the fracture heals. The bone tumor subsequently can be addressed with curettage and bone grafting. Occasionally, because of malalignment, earlier surgical intervention becomes necessary.

Many soft tissue tumors can occur in the hand and digits. Some common benign tumors are giant cell tumors of the tendon sheath, lipomas, and glomus tumors. Lipomas and giant cell tumors of the tendon sheath manifest clinically as painless, slow-growing masses in the palm and digits. Surgical excision is necessary for diagnosis. Glomus tumors arise from the pericytes in the fingertip or subungual area and typically present with intermittent sharp pain in the fingertip. These vascular tumors become intensely symptomatic when the hand is exposed to cold temperatures because of abnormal arteriovenous shunting through the

hypertrophic glomus system. Surgical excision is generally curative and should be preceded by MRI to rule out multifocal sites.

### Infection

The most common infection in the hand is the paronychia. It involves the fold of tissue surrounding the fingernail. *Staphylococcus aureus* is the usual pathogen, introduced by a hangnail, a manicure instrument, or nail biting. Patients present with an exquisitely painful and erythematous swelling involving a part of the nail fold. Occasionally, the infection can progress to surround the nail in a horseshoe fashion and undermine the nail plate. If seen early, within the first 24 to 48 hours, oral antibiotics and local treatment of the finger with warm soaks can be effective. Superficial abscesses can be drained with a sharp blade through the thin skin without requiring local anesthesia. Larger or more chronic infections require surgical drainage.

An infection of the distal pulp of the fingertip, known as a *felon*, is a particular problem in diabetic patients. This infection differs from other subcutaneous infections because of the vertical fibrous septa that divide and stabilize the pulp of the fingertip. Often patients have had some recent penetrating injury in the area. Because of the tightly constrained area of the infection, patients present with an intensely painful fingertip. There may be an area of "pointing" over the abscess. Surgical drainage is required, followed by soaks and oral antibiotics, and intravenous antibiotics are generally recommended in diabetic patients.

Although similar in appearance to a paronychia, herpetic whitlow is caused by herpes simplex virus and must be differentiated from other fingertip infections because of a radically different treatment protocol.[131,132] Whitlow was common among dental hygienists before the widespread use of gloves for all health care workers. It is now most commonly seen in children. As with bacterial infections, the area becomes painful and erythematous; local tenderness is much less severe, however. Diagnosis is ascertained by clinical presentation and history. Vesicles that are seen early can be ruptured for fluid analysis and viral culture. Nonoperative treatment with oral anti-viral agents is recommended.

Other hand and digit infections, such as suppurative flexor tenosynovitis, deep space infections of the palm, pyogenic arthritis, infections from bite wounds, and osteomyelitis, should be evaluated initially with radiographs of the hand and appropriate blood work. If possible, antibiotics should be withheld until definitive cultures are obtained from the affected area. Antibiotics should be administered intravenously, and the hand and wrist should be immobilized. Most infections of this nature require surgical drainage for definitive treatment.

CHAPTER 51

# Temporomandibular Joint Pain

Daniel M. Laskin

**KEY POINTS**

- Temporomandibular joint (TMJ) pain must be distinguished from pain that more commonly arises from the muscles of mastication (myofascial pain), which can produce similar signs and symptoms.
- TMJ pain also must be distinguished from pain that originates in the ear or parotid gland.
- TMJ pain and masticatory muscle pain usually are accompanied by limitation of mouth opening, but pain arising from the ear or parotid gland is not.
- Most major systemic arthropathies can also involve the TMJ and thereby give rise to pain and limited jaw movement.
- Displacement of the intra-articular disk in the TMJ produces pain that is accompanied by a clicking or popping sound or the sudden onset of jaw locking.

Pain in the temporomandibular joint (TMJ) region is a commonly encountered symptom that affects more than 10 million people in North America, and is universally recognized across populations worldwide as a significant health care burden. Because of its diverse causes, however, proper diagnosis and treatment may be difficult to achieve. Because of the proximity of the ear and parotid gland and the similar nature of pain arising from these areas, pathologic conditions involving these structures are often confused with conditions arising in the TMJ. Pain that occurs in the adjacent muscles of mastication, also a frequently encountered situation, not only is similar to TMJ pain in character and location, but also is associated with jaw dysfunction, a common finding with painful conditions directly involving the TMJ. For these reasons, knowledge of the various painful conditions occurring in the TMJ region is essential in establishing a correct diagnosis.

Because patients with primary TMJ disease often have secondary myofascial pain in the muscles of mastication, and because secondary TMJ disease can develop in patients with primary myofascial pain, the generally accepted term used to describe this overlapping group of conditions is *temporomandibular disorders*. These conditions are subdivided for purposes of diagnosis and treatment into conditions that primarily involve the TMJ (TMJ problems) and conditions that primarily involve the muscles of mastication (myofascial pain and dysfunction [MPD], masticatory myalgia). From a diagnostic standpoint, it is important to consider the numerous conditions that mimic the temporomandibular disorders or MPD by producing similar signs and symptoms (Tables 51-1 and 51-2).

Table 51-3 lists the various pathologic entities that commonly involve the TMJ. Although a variety of conditions are known, only three types are considered to generally produce pain: the various arthritides, derangements of the intra-articular disk, and certain neoplasms.

## ARTHRITIS OF THE TEMPOROMANDIBULAR JOINT

Arthritis is the most common painful condition affecting the TMJ. Although osteoarthritis and rheumatoid arthritis are encountered most frequently, cases of infectious arthritis, metabolic arthritis, and TMJ involvement as part of the spondyloarthropathies are also seen in practice. Traumatic arthritis is another relatively common occurrence.

### Osteoarthritis

Osteoarthritis is the most common type of arthritis involving the TMJ and the most frequent cause of pain in that region. Clinical symptoms of the disease have been reported in 16% of the general population,[1] but radiographic features have been found in 44% of asymptomatic individuals.[2] Although the TMJ is not a weight-bearing joint in the same sense as the joints of the long bones, the stresses associated with such parafunctional habits as clenching and grinding of the teeth are sufficient to contribute to similar degenerative changes in some patients.[3] Acute and chronic trauma and derangements of the intra-articular disk also are common causes of secondary degenerative arthritis.

#### Clinical Findings

Primary osteoarthritis, which usually is seen in older individuals, is insidious in its onset; it generally produces only mild discomfort, and individuals rarely complain about the condition. Secondary osteoarthritis usually occurs in younger patients (20 to 40 years old) and tends to be painful. In contrast to primary degenerative joint disease and rheumatoid arthritis, it often is limited to only one TMJ, although it may become bilateral in the late stages, and involvement of other joints is uncommon. The condition is characterized by TMJ pain that is increased by function, joint tenderness, limitation of mouth opening, and occasional clicking and popping sounds. In the late stages, crepitation may be noted in the joint.

**TABLE 51-1** Differential Diagnosis of Nonarticular Conditions Mimicking Temporomandibular Joint Pain or Myofascial Pain in the Masticatory Muscles

| Disorder | Jaw Limitation | Muscle Tenderness | Diagnostic Features |
|---|---|---|---|
| Pulpitis | No | No | Mild to severe ache or throbbing; intermittent or constant; aggravated by thermal change; eliminated by dental anesthesia; positive radiographic findings |
| Pericoronitis | Yes | Possible | Persistent mild to severe ache; difficulty swallowing; possible fever; local inflammation; relieved with dental anesthesia |
| Otitis media | No | No | Moderate to severe earache; constant pain; fever; usually history of upper respiratory infection; no temporomandibular joint tenderness |
| Parotitis | No | No | Constant aching pain, worse when eating; feeling of pressure in ears; absent salivary flow; ear lobe elevated; suppuration from duct |
| Sinusitis | No | No | Constant aching or throbbing; worse with change of head position; nasal discharge; often maxillary molar pain not relieved by dental anesthesia |
| Trigeminal neuralgia | No | No | Sharp stabbing pain of short duration; trigger zone; pain follows nerve pathway; older patient age group; often relieved by dental anesthesia |
| Atypical (vascular) neuralgia | No | No | Diffuse throbbing or burning pain of long duration; often associated autonomic symptoms; no relief with dental anesthesia |
| Temporal arteritis | No | No | Constant throbbing preauricular pain; artery prominent and tender; low-grade fever; may have visual problems; elevated erythrocyte sedimentation rate |
| Trotter's syndrome | Yes | No | Aching pain in ear, side of face, and lower jaw; deafness; nasal obstruction; cervical lymphadenopathy |
| Eagle's syndrome | No | No | Mild to sharp stabbing pain in ear, throat, and retromandible; provoked by swallowing, turning head, carotid compression; usually post tonsillectomy; styloid process >2.5 cm |

Modified from Laskin DM, Block S: Diagnosis and treatment of myofascial pain dysfunction (MPD) syndrome. *J Prosthet Dent* 56:75–84, 1986.

**TABLE 51-2** Differential Diagnosis of Nonarticular Conditions Producing Limitation of Mandibular Movement

| Disorder | Jaw Limitation | Muscle Tenderness | Diagnostic Features |
|---|---|---|---|
| Odontogenic infection | Yes | Yes | Fever; swelling; positive radiographic findings; tooth tender to percussion; pain relieved and movement improved with dental anesthesia |
| Nonodontogenic infection | Yes | Yes | Fever; swelling; negative dental findings on radiograph; dental anesthesia may not relieve pain or improve jaw movement |
| Myositis | Yes | Yes | Sudden onset; jaw movement associated with pain; areas of muscle tenderness; usually no fever |
| Myositis ossificans | No | No | Palpable nodules seen as radiopaque areas on radiograph; involvement of nonmasticatory muscles |
| Neoplasia | Possible | Possible | Palpable mass; regional nodes may be enlarged; may have paresthesia; radiograph may show bone involvement |
| Scleroderma | No | No | Skin hard and atrophic; mask-like facies; paresthesias; arthritic joint pain; widening of periodontal ligament |
| Hysteria | No | No | Sudden onset after psychological trauma; no physical findings; jaw opens easily under general anesthesia |
| Tetanus | Yes | No | Recent wound; stiffness of neck; difficulty swallowing; spasm of facial muscles; headache |
| Extrapyramidal reaction | No | No | Patient on antipsychotic drug or phenothiazine tranquilizer; hypertonic movement; lip smacking; spontaneous chewing motions |
| Depressed zygomatic arch | Possible | No | History of trauma; facial depression; positive radiographic findings |
| Osteochondroma coronoid | No | No | Gradual limitation; jaw may deviate to unaffected side; possible clicking sound on jaw movement; positive radiograph findings |

Modified from Laskin DM, Block S: Diagnosis and treatment of myofascial pain dysfunction (MPD) syndrome. *J Prosthet Dent* 56:75–84, 1986.

### Imaging Findings

The earliest radiologic feature of osteoarthritis of the TMJ, whether primary or secondary, is subchondral sclerosis in the mandibular condyle. If the condition progresses, condylar flattening and marginal lipping may be noted. In the later stages, erosion of the cortical plate, osteophyte formation, or both may occur. Breakdown of the subcortical bone occasionally may result in the formation of so-called *bone cysts*. Although changes in the articular fossa generally are not as severe as changes in the condyle, cortical erosion sometimes can be seen. Narrowing of the joint space also

**TABLE 51-3** Differential Diagnosis of Temporomandibular Joint (TMJ) Diseases

| Disorder | Jaw Limitation | Muscle Tenderness | Diagnostic Features |
|---|---|---|---|
| Agenesis | No | Yes | Congenital; usually unilateral; mandible deviates to affected side; unaffected side long and flat; severe malocclusion; often ear abnormalities; radiograph shows condylar deficiency |
| Condylar hypoplasia | No | No | Congenital or acquired; affected side has short mandibular body and ramus, fullness of face, deviation of chin; body of mandible elongated and face flat on unaffected side; malocclusion; radiograph shows condylar deformity, antegonial notching |
| Condylar hyperplasia | No | No | Facial asymmetry with deviation of chin to unaffected side; cross-bite malocclusion; prognathic appearance; lower border of mandible often convex on affected side; radiograph shows symmetric enlargement of condyle |
| Neoplasia | Possible | Yes | Mandible may deviate to affected side; radiographs show enlarged, irregularly shaped condyle or bone destruction, depending on type of tumor; unilateral condition |
| Infectious arthritis | Yes | No | Signs of infection; may be part of systemic disease; radiograph may be normal early, later can show bone destruction; fluctuance may be present; pus may be obtained on aspiration; usually unilateral |
| Rheumatoid arthritis | Yes | Yes | Signs of inflammation; findings in other joints (hands, wrists, feet, elbows, ankles); positive laboratory test results; retarded mandibular growth in children; anterior open bite; radiograph shows bone destruction; usually bilateral |
| Spondyloarthropathies | | | |
| Psoriatic arthritis | Yes | Yes | Presence of cutaneous psoriasis; nail dystrophy; involvement of distal interphalangeal joints; radiograph shows condylar erosion; negative for rheumatoid factor |
| Ankylosing spondylitis | Yes | Yes | Frequent involvement of the spine and sacroiliac joint; extra-articular manifestations of spondylitis include iritis, anterior uveitis, aortic insufficiency, and conduction defects; erosive condylar changes; TMJ ankylosis may occur |
| Metabolic arthritis | | | |
| Gout | Yes | Yes | Usually sudden onset; often monoarticular; commonly involves great toe, ankle, and wrist; joint swollen, red, and tender; increased serum uric acid; late radiographic changes |
| Pseudogout | Yes | Yes | Generally unilateral; TMJ may be only joint involved; joint frequently swollen; presence of intra-articular calcification; may be a history of trauma |
| Traumatic arthritis | Yes | Yes | History of trauma; radiograph normal except for possible widening of joint space; local tenderness; usually unilateral |
| Degenerative arthritis | Yes | Yes | Unilateral joint tenderness; often crepitus; TMJ may be only joint involved; radiograph may be normal or show condylar flattening, lipping, spurring, or erosion |
| Ankylosis | Yes | Yes | Usually unilateral, but can be bilateral; may be history of trauma; young patient may show retarded mandibular growth; radiographs show loss of normal joint architecture |
| Internal disk derangement | Yes | Yes | Pain exacerbated by function; clicking on opening or opening limited to <25 mm with no click; positive MRI findings; may be history of trauma; usually unilateral |

Modified from Laskin DM, Block S: Diagnosis and treatment of myofascial pain dysfunction (MPD) syndrome. *J Prosthet Dent* 56:75–84, 1986.

occurs in the late stages; this is indicative of concomitant degenerative changes and thinning of the intra-articular disk. Although changes in the TMJ usually can be seen on plain radiographs, sagittal and coronal CT scans are the preferred modality to image the bony structures.

## Diagnosis

The diagnosis of osteoarthritis is made on the basis of the patient's history and the clinical and radiographic findings. The patient often reports a history of trauma or parafunctional oral habits. Involvement is generally unilateral, and no significant changes are observed in any of the other joints. The pain tends to be well localized, and the TMJ is often tender to palpation.

## Treatment

Treatment of degenerative arthritis of the TMJ is usually medical, as in other joints of the body. Treatments involve patient use of nonsteroidal anti-inflammatory drugs, application of heat, eating a soft diet, limitation of jaw function, and use of a bite appliance to control parafunction if the patient has a chronic habit of clenching or grinding the teeth. Arthrocentesis has also been shown to be helpful.[4,5] Physical therapy with thermal agents, ultrasound, and iontophoresis also can be beneficial, and isotonic and isometric exercises are used to improve joint stability after the acute symptoms have subsided. The use of intra-articular steroid injections is controversial; they should be used only in patients with acute symptoms that do not respond to other

forms of medical management. Because of the potentially damaging effects of multiple steroid injections,[4,6] they should be limited to no more than three or four single injections given at 3-month intervals. Intra-articular injection of high-molecular-weight sodium hyaluronate given twice, 2 weeks apart, has been shown to have essentially the same therapeutic effect as a steroid injection, without the potential adverse effects.[5,7]

When the acute symptoms have been controlled, therapy is directed toward control of factors that might contribute to the degenerative process. Unfavorable loading of the joint is eliminated by replacement of missing teeth to establish a good, functional occlusion; correction of any severe dental malrelationships through orthodontics or orthognathic surgery; and continued use of a bite appliance at night to control teeth-clenching or teeth-grinding habits.[6,8]

For patients in whom medical management for 3 to 6 months fails to relieve the symptoms, surgical management may be indicated. Surgery involves removal of the minimal amount of bone necessary to produce a smooth articular surface. Unnecessary removal of the entire cortical plate, as occurs with the so-called *condylar shave* procedure or high condylotomy, can lead to continuation of the resorptive process in some instances, and should be avoided if possible.

## Rheumatoid Arthritis

More than 50% of patients with rheumatoid arthritis have involvement of the TMJ.[9] Although the TMJ may be affected early in the course of the disease, other joints in the body usually are involved first. The approximate female-to-male ratio is 3:1. TMJ involvement may also characterize juvenile inflammatory arthritis. In children, destruction of the mandibular condyle by the disease process results in growth retardation and facial deformity characterized by a severely retruded chin. Fibrous or bony ankylosis is a possible sequel at all ages.

### Clinical Findings

Patients with rheumatoid arthritis of the TMJ have bilateral pain, tenderness, swelling in the preauricular region, and limitation of mandibular movement. These symptoms are characterized by periods of exacerbation and remission. Joint stiffness and pain are usually worse in the morning and decrease during the day. The limitation in mandibular movement worsens as the disease progresses; an anterior open bite may also develop in the patient.

### Imaging Findings

Although radiographic changes may not be noted in the early stages of the disease, approximately 50% to 80% of patients show bilateral evidence of demineralization, condylar flattening, and bone erosion while the disease progresses, so the articular surface appears irregular and ragged. Erosion of the glenoid fossa also might also be seen. Narrowing of the joint space is caused by destruction of the intra-articular disk. With continued destruction of the condyle, loss of ramus height can lead to contact of only the posterior teeth and an anterior open bite. Increasingly, MRI is used as an additional modality for the detection of articular damage, synovitis, or both, or of involvement of adnexal structures.

### Diagnosis

Rheumatoid arthritis is diagnosed on the basis of the patient's history, clinical and radiographic findings, and confirmatory laboratory tests. Distinguishing features for rheumatoid arthritis and degenerative arthritis of the TMJ are shown in Table 51-3.

### Treatment

Treatment of rheumatoid arthritis of the TMJ is similar to that provided for other joints.[7,10] Anti-inflammatory drugs are used during the acute phases, and mild jaw exercises are used to prevent excessive loss of motion when acute symptoms subside. In severe cases, disease-modifying drugs, such as methotrexate, and biologic agents, including TNF inhibitors, abatacept, tocilizumab, and rituximab, may be used pending systemic presentation. Orthognathic surgery may be necessary in patients with an anterior open bite after the disease goes into remission, or in patients in whom ankylosis develops after that condition is corrected.

## Spondyloarthropathies

In addition to the adult and juvenile forms of rheumatoid arthritis, psoriatic arthritis, ankylosing spondylitis, and reactive arthritis also can involve the TMJ.[8-13]

### Psoriatic Arthritis

Psoriatic arthritis occurs in approximately one-third of patients who have cutaneous psoriasis (see Chapter 77). This disorder has a sudden onset, can be episodic in nature, and may show spontaneous remission.[9,12] Often only one TMJ is involved. Symptoms include TMJ pain and tenderness, restricted jaw movement, and crepitation, mimicking the symptoms of rheumatoid arthritis.[9,12] Radiographic changes are nonspecific and cannot be distinguished easily from those of other types of arthritis, particularly rheumatoid arthritis and ankylosing spondylitis.[13,14] They usually involve erosive changes in the condyle and glenoid fossa associated with extreme narrowing of the joint space.[11,15,16] In severe cases, ankylosis may develop, reflected occasionally in new bone formation at earlier stages.[12,17]

The physician usually diagnoses psoriatic arthritis on the basis of the triad of psoriasis, radiographic evidence of erosive arthritis, and a negative serologic test for rheumatoid factor. Even in the presence of a rash, however, the diagnosis cannot be absolutely confirmed. The differential diagnosis always should include rheumatoid arthritis, reactive arthritis, ankylosing spondylitis, and gout.

Treatment of psoriatic arthritis of the TMJ is as described in Chapter 77 and is driven essentially by the imperative to treat the systemic inflammatory disease process.[13,18-21] Surgery is necessary if ankylosis occurs.

### Ankylosing Spondylitis

TMJ involvement develops in approximately one-third of patients with ankylosing spondylitis several years after onset of the disease. Pain and limitation of jaw movement are the most common symptoms, and ankylosis can develop in advanced cases.[8,11,14,22] On radiographic examination, approximately 30% of patients show erosive changes in the condyle and fossa and narrowing of the joint space.[15,23] In long-standing cases, a more florid osteophytic response is sometimes seen during quiescent periods. The severity of the changes seems to be related to the severity of the disease. Treatment of ankylosing spondylitis of the TMJ is generally medical and is part of the total management of the patient. Physical therapy is used to improve jaw mobility, and a bite appliance is used, when indicated, to reduce parafunctional stress on the joint. If ankylosis develops, surgery is the treatment of choice.[24]

### Reactive Arthritis

Reactive arthritis of the temporomandibular joint is more common in males than in females. It is characterized by recurrent pain, swelling, and limitation of mouth opening.[25] Radiographically, condylar erosion may be evident.[26] Treatment is similar to that of the other seronegative spondyloarthropathies, consisting of nonsteroidal anti-inflammatory drugs, intra-articular steroids, and disease-modifying drugs. If a specific triggering bacterial infection can be identified, an appropriate antibiotic should be prescribed.

## Traumatic Arthritis

Acute trauma to the mandible that does not result in a fracture can still produce injury to the TMJ. When this occurs in a child, it is essential to warn the parents about the possibility of future retardation of mandibular growth and associated facial deformity resulting from damage to the articular cartilage, which is an important growth site.[16,27]

Traumatic arthritis is characterized by TMJ pain and tenderness and limitation of jaw movement. The resultant inflammation and occasional hemarthrosis can lead to loss of tooth contact on the affected side. Frequently, bruises or lacerations are apparent at the site of the initial injury. No radiographic changes may be seen, or widening of the joint space may be produced by intra-articular edema or hemorrhage. In some instances, radiographs may show an intracapsular fracture that was not recognized on clinical examination.

Treatment of traumatic arthritis consists of the use of nonsteroidal anti-inflammatory drugs, application of heat, a soft diet, and initial restriction of jaw movement. When acute symptoms subside, range-of-motion exercises should be used to avoid fibrous ankylosis.

## Infectious Arthritis

Infectious arthritis rarely involves the TMJ. Although it can affect the joint as part of such systemic diseases as gonorrhea, syphilis, tuberculosis, and Lyme disease,[17,18,28,29] the most common way is by direct extension of an adjacent infection of dental, parotid gland, or otic origin.[19,30] Occasionally, it also may occur from localization of blood-borne organisms in the joint after a traumatic injury or by direct involvement through a penetrating wound.[20,30] The most common pathogens are *Staphylococcus aureus*, *Haemophilus influenzae*, and *Streptococcus* species.[31]

### Clinical Findings

Infectious arthritis generally results in unilateral pain, tenderness, swelling, and redness in the region of the TMJ. Chills, fever, sweating, and systemic findings characteristic of the specific type of infection also are present. Often the patient's teeth cannot be occluded because of swelling within the joint. In pyogenic forms of infectious arthritis, fluctuation may be noted in the joint region. Patients with Lyme disease show characteristic skin lesions and, often, positive serology.[18,29]

### Imaging Findings

Radiographic findings are usually normal in early stages of the disease because of lack of bony involvement, but the intra-articular accumulation of pus or inflammatory exudate may cause separation of articulating surfaces, which can be detected on MRI. Later, depending on the severity and chronicity of the infection, varying degrees of bony destruction, ranging from damage to the articular surface of the mandibular condyle to extensive osteomyelitis, may be seen. In the late stages, fibrous or bony ankylosis may occur. In children, infectious arthritis can affect growth of the condyle, resulting in facial asymmetry.

### Treatment

Treatment of infectious arthritis includes the use of appropriate antibiotics, proper hydration, control of pain, and limitation of jaw movement. Arthrocentesis with Ringer's solution one to three times weekly until acute symptoms subside has also been recommended.[32] Suppurative infections may require aspiration, incision and drainage, or sequestrectomy. When bone loss is extensive, reconstructive procedures may be necessary. In children in whom mandibular growth has been affected, a costochondral graft can be used to correct facial asymmetry and re-establish growth of the mandible.

## Metabolic Arthritis

Metabolic arthritis, which can accompany gout or pseudogout (calcium pyrophosphate dehydrate arthropathy), is rare in the TMJ.[21,33]

### Gout

Gouty arthritis of the TMJ occurs most frequently in men older than 40 years and usually is preceded by involvement of one or more joints of the feet or hands. The attack usually occurs suddenly, and the joint becomes swollen, painful, red, and tender. Recovery may occur in a few days, and remission can last for months to years.

When attacks are infrequent, radiographic changes may not be noted for a long time. Because so few cases have been

reported, the precise radiographic changes that occur have not been well documented. Calcified areas in the disk, destruction of the hard tissues of the joint, condylar exostoses and spurring, and the presence of tophi have been described.[21,33-35] The initial approach to treatment of gout involving the TMJ is medical. If symptoms are not controlled, however, surgical débridement of the joint and arthroplasty may be indicated.

### Pseudogout

Calcium pyrophosphate dehydrate arthropathy (pseudogout) in the TMJ clinically mimics gout, and the mandibular condyle may show degenerative and erosive changes radiographically. In the primary form, which usually is seen in older patients, intra-articular calcification is noted (chondrocalcinosis), and diffuse calcification occurs in the intra-articular disk.[21-25,36-39] Similar changes are seen in the secondary form, but it occurs in younger patients and frequently is preceded by a history of trauma. Fine-needle aspiration can help distinguish pseudogout from gout. In gout, under polarizing microscopy, the crystals are needle shaped and there is negative birefringence; in pseudogout the crystals are rhomboid/rod shaped and weakly birefringent.

Just as in gout of the TMJ, the initial treatment of pseudogout is medical, and surgery is reserved for patients in whom such treatment is ineffective.

## INTERNAL DERANGEMENTS

Internal derangements are a common cause of pain in the TMJ. They represent a disturbance in the normal anatomic relationship between the intra-articular disk and the condyle, resulting in interference with the smooth movement of the joint.

### Clinical Findings

Three stages of internal derangement have been identified: (1) a painless inco-ordination phase, in which a momentary catching sensation is felt during mouth opening; (2) anterior disk displacement with reduction into the normal position during mouth opening, which is characterized by a clicking or popping sound (Figure 51-1); and (3) anterior disk displacement without reduction on attempted mouth opening, which is characterized by restriction of jaw movement, or locking (Figure 51-2). Joint pain in patients with anterior disk displacement, with or without reduction, is caused by condylar compression of the highly innervated retrodiskal tissue that occupies the glenoid fossa while the intra-articular disk assumes a more forward position, and by the accompanying inflammation.

### Etiology

The three main causes of internal derangement of the intra-articular disk are trauma, abnormal functional loading of the joint, and degenerative joint disease.[26,40] Although some clinicians believe that occlusal factors also play a role in causing internal derangements, no conclusive studies have shown such a relationship.

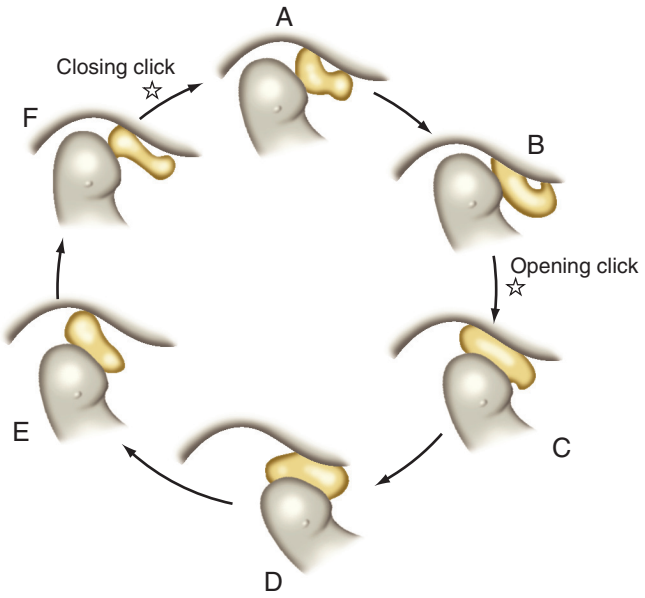

**Figure 51-1** Anterior displacement of the intra-articular disk with reduction on opening of the mouth. A clicking or popping sound occurs as the disk returns to its normal position in relation to the condyle. During closure, the disk again becomes anteriorly displaced, sometimes accompanied by a second sound (reciprocal click). *(Modified from McCarty W: Diagnosis and treatment of internal derangements of the articular disc and mandibular condyle. In Solberg WK, Clark GT, editors:* Temporomandibular joint problems: biologic diagnosis and treatment, *Chicago, 1980, Quintessence, p 155.)*

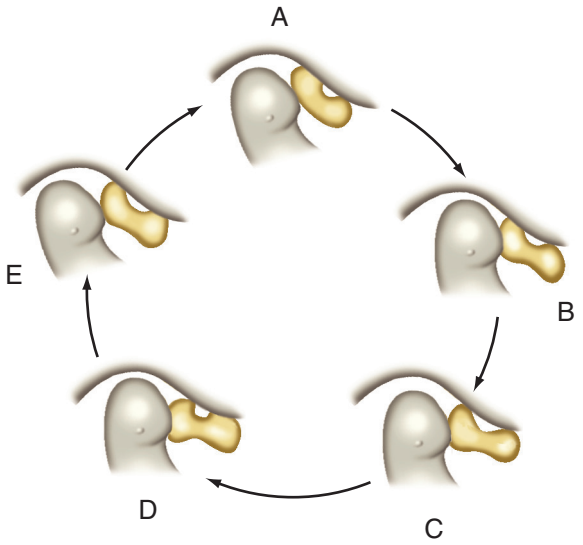

**Figure 51-2** **A-E,** Anterior displacement of the intra-articular disk without reduction on attempted mouth opening. The displaced disk acts as a barrier and prevents full translation of the condyle. *(Modified from McCarty W: Diagnosis and treatment of internal derangements of the articular disc and mandibular condyle. In Solberg WK, Clark GT, editors:* Temporomandibular joint problems: biologic diagnosis and treatment, *Chicago, 1980, Quintessence, p 151.)*

Acute macrotrauma is probably the most common cause of internal derangement. Among the events thought to cause macrotrauma are a blow to the jaw, endotracheal intubation, cervical traction, and iatrogenic stretching of the joint during dental or oral surgical procedures. Although whiplash injuries frequently have been implicated in the

development of internal derangement, a study of 155 patients with this type of injury showed that clicking in the TMJ immediately after the automobile accident developed in only one patient.[27,41] At 1 month of follow-up, two additional patients of the 129 contacted experienced clicking, but at 1 year, no additional patients of the 104 contacted had developed clicking. Although internal derangements of the TMJ can be caused by a whiplash injury, the incidence seems to be low.

Whether a patient manifests alterations in the articular surface leading to a catching or binding sensation, anterior disk displacement with reduction on mouth opening (clicking or popping), or anterior disk displacement without reduction during mouth opening (locking) after trauma to the TMJ depends on the severity of the injury. Although associated traumatic arthritis causes pain during function in each of these instances, the pain is more severe in the last two conditions because of compression of retrodiskal tissue, which is now located in the articular zone.

Functional overloading of the TMJ associated with the habit of chronic teeth clenching is another frequent cause of internal derangements. Although the TMJ is constructed for eccentric movements, it is not constructed for the constant isometric loading and unloading that occurs during this activity. Such parafunction affects the lubrication of the joint and alters the articular surfaces, introducing friction between the disk and the condyle that leads to degenerative changes in the articular surfaces and results in gradual anterior displacement of the disk.[26,28,40,42]

Degenerative joint disease may precede the development of an internal derangement, or it may occur after the development of an internal derangement. In the first instance, changes in the character of the articulating surfaces result in an inability of the parts to glide smoothly over each other, gradually leading to forward displacement of the disk, which normally rotates posteriorly during mouth opening. In the second instance, the displaced disk results in an altered relationship between articulating components of the joint, which leads to degenerative changes in these structures. In patients in whom the condition causing the degenerative joint disease is still active, whether primarily or secondarily, both the causative condition and the disk derangement must be treated for the problem to be resolved completely.

## Imaging Findings

Depending on the cause of the internal derangement and its duration, radiographs may or may not show any evidence of degenerative joint disease. MRI shows anterior disk displacement in the closed mouth position, as well as a return to a normal disk relationship during mouth opening, in patients with clicking and popping. However, in patients with locking, the disk remains in the anterior position on attempted mouth opening, and movement of the condyle is limited. In a small group of patients with locking, MRI showed the intra-articular disk in normal position when the teeth are in occlusion, rather than in anterior displacement, and no change in disk position occurs when the patient attempts to open the mouth.[29,43] In such cases, adhesion of the disk to the articular eminence prevents translation of the condyle. These patients differ from those with anteriorly displaced, non-reducing disks in that they do not have a history of TMJ clicking that precedes the sudden onset of locking.

## Treatment

Initial treatment of patients with painful clicking or popping in the TMJ consists of a nonsteroidal anti-inflammatory drug; a soft, nonchewy diet; and use of a bite-opening appliance to reduce compression of retrodiskal tissue (Figure 51-3). A muscle relaxant drug can be added to the regimen if the patient has associated myofascial pain. When the pain has stopped, no further treatment is generally necessary, although joint noise still may be present. However, in patients who have teeth-clenching and -grinding habits, use of a bite appliance is indicated at night to control these habits and prevent recurrence of the pain.

A long-term follow-up study (1 to 15 years) of 190 patients with a history of clicking treated by such conservative nonsurgical modalities, which are not directed specifically to the problems of joint noise or disk displacement, showed that the condition worsened in only 1% of patients, indicating that it is permissible to observe individuals with painless clicking as long as they remain otherwise asymptomatic.[30,44]

In patients with pain and clicking in the TMJ that is unresponsive to nonsurgical management, the disk should be repositioned arthroscopically or by open surgery (diskoplasty). Patients with parafunctional habits should continue the use of a bite appliance when sleeping. In patients with locking (anterior disk displacement without reduction), whether painful or not, treatment is urgent because if the condition is left untreated for a long time, subsequent management can be complicated by further degenerative changes in the disk and condyle that make disk salvage (diskoplasty) impossible. Initial treatment involves joint lavage and lysis of adhesions by arthrocentesis or arthroscopically. The former involves establishment of inlet and outlet portals in the upper joint space with hypodermic needles,

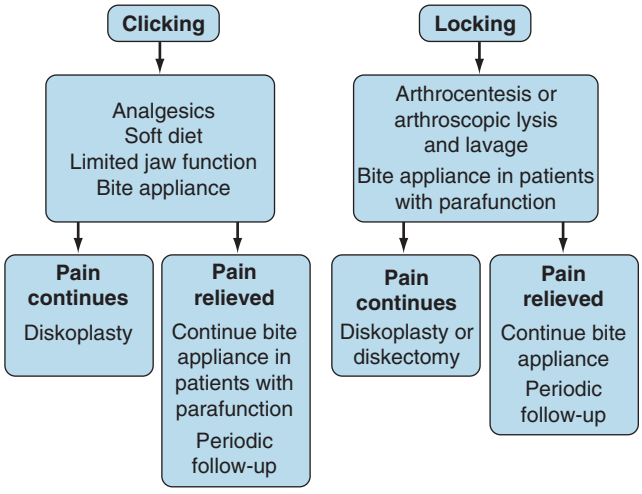

**Figure 51-3** Management of internal derangements of the temporomandibular joint. Patients with painful clicking or locking are treated medically initially, whereas patients with locking require surgical intervention.

irrigation with lactated Ringer's solution to remove inflammatory tissue breakdown products and cytokines, and lysis of adhesions by hydraulic distention and manual manipulation of the joint (Figure 51-4).[31,45]

The results of arthrocentesis parallel those achieved with arthroscopic lysis and lavage, and the procedure is less invasive. Although neither of these procedures restores the disk to its normal position, they do restore disk and joint mobility, and they reduce pain and improve function in most patients.[32,33,46,47] In these patients, the retrodiskal tissue within the joint undergoes fibrosis and acts as a pseudodisk. It is important that patients who have teeth-grinding or -clenching habits are prescribed a bite appliance postoperatively to wear while sleeping.

In patients who do not respond favorably to arthrocentesis or arthroscopy, the displaced disk should be repositioned by an open operation. If the disk is extremely deformed and cannot be repositioned, or if a large, nonreparable perforation in the disk or a tear in the retrodiskal tissue is present, the disk should be removed. Although autogenous auricular cartilage or dermal grafts, or temporalis muscle flaps, have been used as disk replacements, results have been unpredictable.[31,45,48] More recent long-term studies have shown that most patients can tolerate a diskless joint.[34,49] Currently, no acceptable alloplastic substitutes for the disk are available.

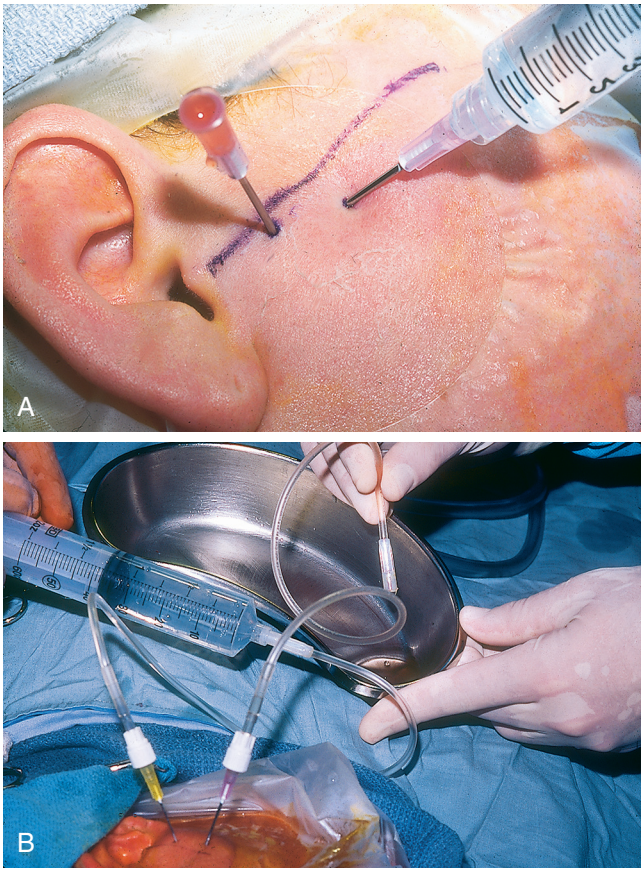

**Figure 51-4** Temporomandibular joint arthrocentesis. **A,** Hypodermic needles inserted into the upper joint space to allow lavage of the joint. **B,** Joint is being irrigated with lactated Ringer's solution.

## NEOPLASMS

Although primary neoplasms involving the TMJ are uncommon, they must be considered in the differential diagnosis of painful conditions affecting this region.[35,36,50,51] Chondroma, osteochondroma, and osteoma are the most frequently encountered benign tumors, but isolated cases of fibro-osteoma, myxoma, fibrous dysplasia, giant cell reparative granuloma, aneurysmal bone cyst, synovioma, synovial chondromatosis, chondroblastoma, osteoblastoma, glomus tumor, and synovial hemangioma have been reported. Malignant tumors of the TMJ are even rarer, with infrequent reports of fibrosarcoma, chondrosarcoma, synovial fibrosarcoma, osteosarcoma, malignant fibrous histiocytoma, malignant schwannoma, leiomyosarcoma, and multiple myeloma. The TMJ also can be invaded by neoplasms from the cheek, the parotid gland, the external auditory canal, and the adjacent ramus of the mandible. Metastasis to the condyle from distant neoplasms in the breast, lung, prostate, colon, thyroid gland, liver, stomach, and kidney has been described.

Tumors of the TMJ can cause pain, limitation of jaw movement, deviation of the mandible to the affected side on attempted mouth opening, and difficulty in occluding the teeth. Depending on the nature of the condition, radiographs may show bony deformation, apposition, or resorption. A biopsy is necessary to establish the definitive diagnosis.

## MYOFASCIAL PAIN AND DYSFUNCTION

MPD, or masticatory myalgia, is considered to be a psychophysiologic disease that primarily involves the muscles of mastication, and not the TMJ. Women are affected more frequently than men; the ratio in various reports ranges from 3:1 to 5:1. Although the condition can occur in children, the incidence seems to be greatest in adults 20 to 40 years old. MPD frequently is confused with painful conditions that affect the TMJ, such as degenerative arthritis or internal derangements; patients with primary MPD can develop these diseases secondarily, and patients with primary joint disease can develop secondary MPD. Enhanced understanding of the causes and pathogenesis of this condition makes its diagnosis easier and its treatment more effective.[37,38,52,53]

### Etiology

Psychological stress has been suggested as an important contributing factor in the development of MPD (psychophysiologic theory).[39,54,55] It is hypothesized that in most patients, stress-related, centrally induced increases in muscle activity, frequently combined with the presence of parafunctional habits such as clenching or grinding of the teeth, may result in associated muscle fatigue, pain, and limited mouth opening.[40,54] However, similar symptoms occasionally have been seen to result from muscle overextension, muscle overcontraction, or trauma (Figure 51-5). A counter-theory (the pain adaptation theory of Lund)[56] has been proposed to suggest that pain in the masticatory muscles leads to a reduction rather than an increase in muscle activity as a protective mechanism, and this reduction causes the

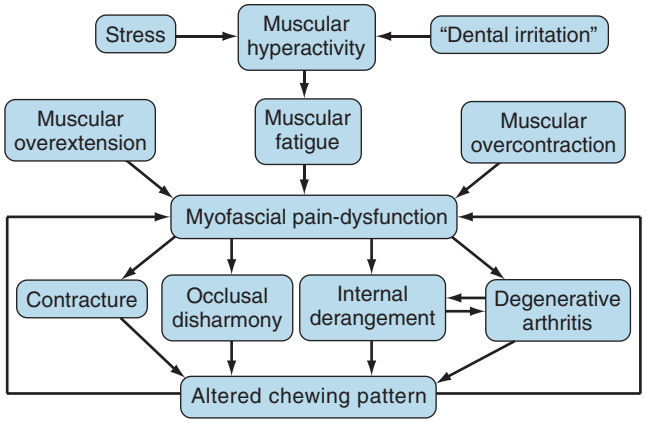

**Figure 51-5** Causes of myofascial pain and dysfunction. Although the diagram shows three pathways, the one involving psychological stress is most common. The mechanism by which stress leads to myofascial pain and dysfunction is termed the *psychophysiologic theory. (Modified from Laskin DM: Etiology of the pain-dysfunction syndrome.* J Am Dent Assoc *79:147–153, 1969. Copyright 1969 American Dental Association. Reprinted by permission of ADA Publishing Co.)*

limitation in mouth opening; however, this theory does not explain the origin of the pain. Despite extensive research, the cause of myofascial pain and dysfunction remains unknown.

## Clinical Findings

Pain of unilateral origin is the most common symptom of MPD. In contrast to the pain associated with joint disease, which is well localized, the pain of muscle origin is more diffuse. The patient generally is unable to identify accurately the specific site involved; this can serve as an important diagnostic criterion in distinguishing between muscle and joint disorders.

Depending on the muscle involved, the pain associated with MPD may be described by the patient in various ways. The masseter is the muscle most frequently involved, and the patient usually refers to the pain as a *jaw ache*. The temporalis is the next most commonly involved muscle; it produces pain on the side of the head, which is interpreted by the patient as a headache. Involvement of the lateral pterygoid muscle produces earache or a deep pain behind the eye, whereas medial pterygoid involvement causes discomfort on swallowing and the feeling of a painful, swollen gland beneath the angle of the mandible. Medial pterygoid involvement can cause stuffiness or a full feeling in the ear.

The pain associated with MPD is usually constant, but it is often more severe on arising in the morning or may worsen gradually as the day progresses. Pain generally is exacerbated by jaw function, especially during such activities as eating and excessive talking. Myofascial pain tends to be regional rather than local, and patients with a long-standing problem may complain that pain in the facial region has spread to the cervical area and later to the shoulders and back.

Tenderness in the muscles of mastication, another common finding, can be used to confirm the source of the pain in muscles that are accessible to palpation (masseter, temporalis, and medial pterygoid). Although muscle tenderness usually is not reported by the patient, this symptom can be elicited easily by the examiner. The most frequent sites of tenderness are near the angle of the mandible, in the belly and the posterosuperior aspect of the masseter, in the anterior temporal region, and over the temporal crest on the anterior aspect of the coronoid process. The location of some of the tender areas suggests that tendons also may be a source of pain and tenderness.

Limitation of mandibular movement is the third cardinal symptom of MPD. It manifests as an inability to open the mouth as wide as usual and as a deviation of the mandible to the affected side when mouth opening is attempted. Lateral excursion to the unaffected side is also reduced. The limitation of mandibular movement usually is correlated with the amount of pain present.

A clicking or popping sound in the TMJ is another finding in some patients with MPD. This is not a cardinal sign, however, because it occurs only in patients with a chronic teeth-clenching habit, which gradually produces frictional changes in the joint and subsequent disk displacement.[26,40] The presence of joint sounds alone is insufficient to allow a diagnosis of MPD. Joint sounds must be accompanied by myofascial pain and tenderness in the masticatory muscles that began before the onset of the joint noise. Such patients must be distinguished from patients with a primary internal derangement, in whom muscle splinting produces myofascial pain and tenderness after the onset of the joint noise. The history and differences in physical findings are helpful in making this distinction.

In addition to the three cardinal symptoms of pain, muscle tenderness, and limitation of mouth opening, patients with MPD usually have no clinical or radiographic evidence of pathologic changes in the TMJ. These negative characteristics are important for the physician in establishing the diagnosis because they confirm that the primary site of the problem is not the articular structures.

## Diagnosis

Because the cardinal signs and symptoms of MPD are similar to those produced by such organic problems involving the TMJ as degenerative joint disease and internal disk derangement and by a variety of nonarticular conditions (see Tables 51-1 and 51-2), diagnosis of this condition can be difficult. To make a diagnosis, the physician needs a careful patient history and a thorough clinical evaluation. Periapical radiographs of the teeth and a screening radiograph (panoramic) of the TMJs can be helpful to eliminate dental problems or gross joint disease. If screening views of the TMJs show some abnormality, CT scans are usually advisable for confirmation. MRI also can be useful in determining the position of the disk when an internal derangement of the TMJ is being considered. Depending on the suspected condition, other radiographic views of the head and neck and scintigraphy may be needed to establish a final diagnosis.

Certain laboratory tests may be helpful in some instances. These include a complete blood cell count if an infection is suspected; serum calcium, phosphorus, and alkaline phosphatase measurements for possible bone disease; serum uric acid determination for gout; serum creatinine and creatine kinase levels to detect muscle disease; and erythrocyte

**TABLE 51-4** Distinguishing Features of Myofascial Pain and Fibromyalgia

| | Myofascial Pain | Fibromyalgia |
|---|---|---|
| Patient age distribution | 20-40 years | 20-50 years |
| Gender distribution | Mainly women | Mainly women |
| Distribution of pain | Localized; usually unilateral | Generalized; bilaterally symmetric |
| Tender points | Few | Multiple |
| Trigger points | Uncommon | Common |
| Fatigue | Localized muscle fatigue | Generalized fatigue |
| Sleep disturbance | Common | Common |

sedimentation rate, rheumatoid factor, latex fixation, and anti-nuclear antibody tests for suspected rheumatoid arthritis. Electromyography can be used to evaluate muscle function. Psychological evaluation and psychometric testing are good research tools, but they have little diagnostic value other than to identify the presence of associated abnormal behavioral characteristics.

Fibromyalgia is a condition that sometimes is confused with myofascial pain, particularly when MPD involves several regions in addition to the face. Although fibromyalgia may eventually develop in a a small subset of patients with MPD, these are probably distinct conditions.[41,57] Table 51-4 lists the distinguishing characteristics of myofascial pain versus fibromyalgia.

## Treatment

Treatment of MPD is divided into four phases.[42,58] When a definitive diagnosis is made, phase I therapy should be started (Figure 51-6). Phase I therapy initially involves providing the patient with some understanding of the problem. Because patients often have difficulty accepting a psychophysiologic explanation for their condition, the physician's discussion with the patient should deal first with the issue of muscle fatigue as the cause of the pain and dysfunction, and delay consideration of the role of stress and psychological factors until the symptoms have improved and the patient's confidence has been gained. Associating the symptoms to the specific masticatory muscles from which they arise helps the patient understand the reason for the type and location of the pain—headache from the temporalis muscle, jaw ache from the masseter muscle, discomfort on swallowing and stuffiness in the ear from the medial pterygoid muscle, and earache and pain behind the eye from the lateral pterygoid muscle.

In addition to the initial explanation, the patient should be counseled regarding home therapy. This counseling includes recommendations to avoid clenching and grinding of the teeth, to eat a soft diet, to use moist heat and massage on the masticatory muscles, and to limit jaw movement. A nonsteroidal anti-inflammatory drug should be prescribed for the pain. In patients who have problems sleeping, a small dose of amitriptyline at bedtime is helpful to improve sleep and reducing parafunction.

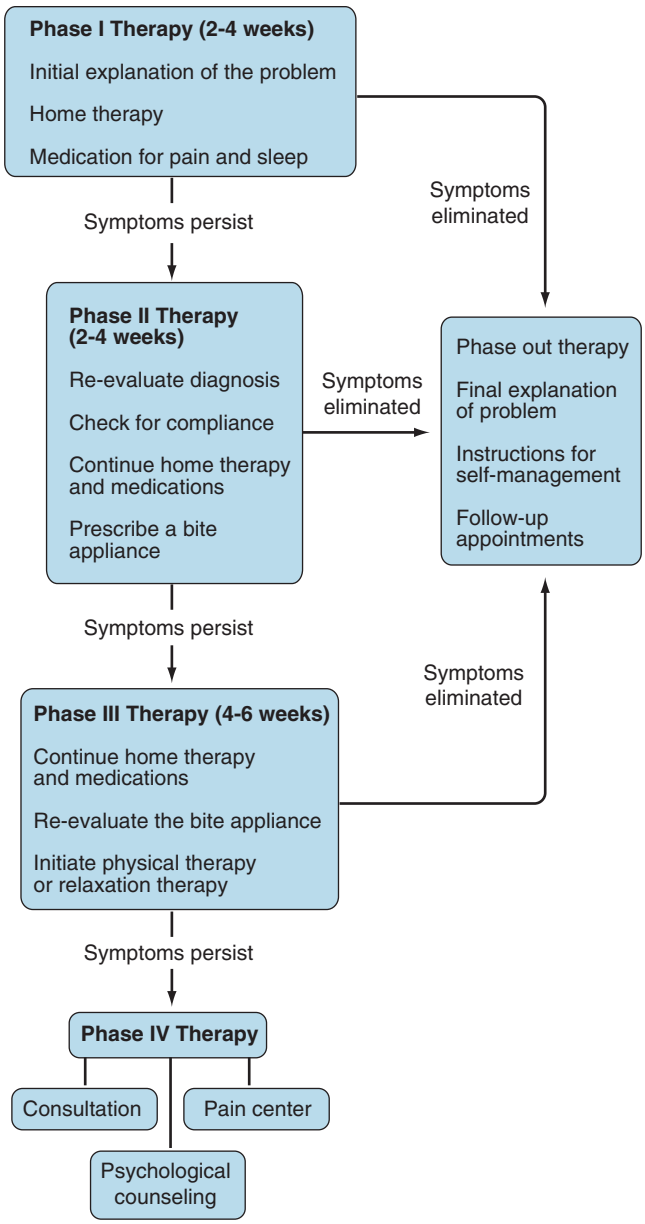

**Figure 51-6** Management of myofascial pain and dysfunction. The treatments are divided into four phases. If the symptoms are eliminated in any of the first three phases, the ongoing therapy is gradually phased out, and the patient is instructed in continued self-management of the condition. *(Modified from Laskin DM, Block S: Diagnosis and treatment of myofascial pain dysfunction [MPD] syndrome.* J Prosthet Dent *56:75–84, 1986.)*

Approximately 50% of these patients experience resolution of their symptoms within 2 to 4 weeks with phase I therapy. For patients whose symptoms persist, phase II therapy is initiated. Home therapy and medications are continued, and a bite appliance is made for the patient. Although numerous types have been used, the Hawley-type maxillary appliance is probably the most effective because it prevents contact of the posterior teeth and thus prevents most forms of parafunctional activity (Figure 51-7).[43,59] The appliance generally is worn at night, but it can be worn for 5 to 6 hours during the day, if necessary. The appliance

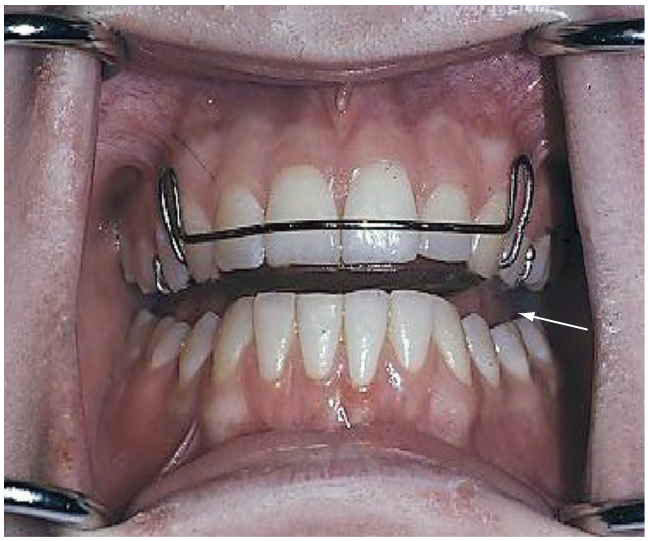

**Figure 51-7** Hawley-type maxillary bite appliance. Only the anterior teeth contact the appliance, and space between the posterior teeth is evident *(arrow)*.

should not be worn continuously, however, because the posterior teeth may supraerupt in some patients.

With phase II therapy, another 20% to 25% of patients become symptom free in 2 to 4 weeks. When the patient becomes symptom free, the medications are stopped first, and use of the bite appliance is discontinued next. If the patient has a return of symptoms, and the appliance is worn only at night, its use can be continued indefinitely.

Patients who do not respond to the use of a bite appliance are entered into phase III treatment for 4 to 6 weeks. In this phase, physical therapy (heat, massage, ultrasound, and electrogalvanic stimulation)[60] or relaxation therapy (electromyographic biofeedback and conditioned relaxation)[61] is added to the regimen. No evidence shows that one form of treatment is better than another, and either can be used first. If one is unsuccessful, the other can be tried. Phase III therapy usually helps another 10% to 15% of patients.

If all of these approaches fail, and no question arises about the correctness of the diagnosis, psychological counseling is recommended. This counseling involves helping patients to identify possible stresses in their lives and learning to cope with such situations. If the diagnosis is in doubt, the patient should be referred first for appropriate dental and neurologic consultation and re-evaluation. Another alternative is to refer patients with recalcitrant MPD to a TMJ center or pain clinic because such patients generally require a multidisciplinary approach for successful treatment.

## CONCLUSION

Successful management of patients with temporomandibular disorders depends on an accurate diagnosis of the disorder and use of the proper therapy based on the physician's understanding of the cause of the patient's condition. Of particular importance is distinguishing patients with MPD, who constitute the majority of patients encountered and who are not surgical candidates, from patients with TMJ disease, who frequently require surgical treatment. Even in the latter group, many commonly encountered conditions, such as arthritis and internal disk derangements, often respond to nonsurgical therapy, and this type of treatment should be given a fair trial before more aggressive management is considered.

CHAPTER 52

# Fibromyalgia

Leslie J. Crofford

**KEY POINTS**

- **Fibromyalgia (FM) is a disorder of centrally amplified and maintained musculoskeletal pain with evidence of altered pain processing in the spinal cord and brain.**
- **Although pain is the defining symptom of FM, fatigue, unrefreshing sleep, dyscognition, depression, and anxiety also have a significant impact on health-related quality of life.**
- **The diagnosis of FM relies on patient report using one of several valid criteria sets.**
- **Patients with other rheumatic diseases have a higher prevalence of FM than the general population, and the presence of comorbid FM affects assessment of disease activity.**
- **It is important to identify FM in order to develop an overall treatment plan that addresses the different mechanisms responsible for musculoskeletal pain.**

Fibromyalgia (FM) is a disorder characterized by chronic, widespread musculoskeletal pain often associated with debilitating fatigue, unrefreshing sleep, dyscognition, depression, and anxiety.[1] Patients with FM have evidence of disordered sensory processing as manifested by widespread allodynia (i.e., pain elicited by an innocuous stimulus that is not usually painful) and hyperalgesia (i.e., exaggerated pain elicited by a noxious stimulus). Patients often have a personal and family history of regional or visceral pain, such as migraine or tension headaches, temporomandibular disorder, irritable bowel syndrome, interstitial cystitis, pelvic pain syndromes, and depression or anxiety.[1-3] A careful history typically reveals a pain-prone phenotype with musculoskeletal pain as only one of the affected body regions.[1] The genetic vulnerability to FM and other disorders characterized by amplified pain is associated with polymorphisms in genes involving pain transmission, neurotransmitter, and stress-response pathways.[4-6] It is thought that in vulnerable persons, triggering events involving activation of sensory nociceptors lead to long-term changes in pain transmission and descending inhibitory pathways.[5] This concept of centrally maintained or amplified pain as the central physiologic alteration in FM has led to treatment strategies that differ from traditional anti-inflammatory or analgesic approaches to musculoskeletal pain.[1] Cognitive and emotional factors also play a significant role in the impact of FM on health, requiring the clinician to address the patient's beliefs and behaviors that augment pain symptoms. In some patients, a multidisciplinary approach to treatment will provide significant benefits.[7]

Because the diagnosis of FM relies solely on patient report and all of the symptoms of FM exist in a continuum in healthy persons, significant controversy has existed regarding the legitimacy of FM as a medical illness.[8] What is clear is that pain reports of persons with FM are associated with activation of areas in the brain associated with pain transmission, as determined by advanced neuroimaging studies.[9] Thus objective evidence of the veracity of the subjective report of pain exists. From a practical perspective, the treating clinician should be able to identify the symptoms of FM and sort through the differential diagnosis, understand its relationship to comorbid rheumatic diseases, assist the patient in distinguishing central pain from mechanical or inflammatory pain, and provide management approaches that address patient symptoms.

## HISTORICAL PERSPECTIVE

Descriptions of patients with symptoms of FM in the medical literature go back centuries. In early descriptions, the condition was often called "muscular rheumatism" to distinguish it from "articular rheumatism."[10] In 1815, Dr. William Balfour, a surgeon from Edinburgh, described nodules and suggested that inflammation in muscle connective tissue was the cause for nodules and pain. He also first reported focal tenderness, referred to as *tender points*, in 1824. Sir William Gowers coined the term *fibrositis* in 1904, sharing in the belief that patients experienced inflammation of fibrous connective tissue that led to tender points in patients with muscular rheumatism.[11]

An interesting historical treatise by Dr. Philip Hench and Edward Boland published in 1946 described the management of rheumatic diseases in U.S. Army soldiers and provides insights that remain relevant in more modern times.[12] They report that muscular rheumatism occurred in 13% of soldiers from the First World War (April 1, 1917 to December 31, 1919). Specialized rheumatism centers were established in the 1940s for soldiers of the Second World War. Hench and Boland published the incidence of rheumatic diseases in the first 1000 cases and differentiated "psychogenic rheumatism," occurring in 20%, from "fibrositis," which included regional syndromes such as bursitis and tendonitis, occurring in 13.4%. Hench and Boland noted that most of the patients sent to these specialized centers with muscular rheumatism did not have myositis or

fibrositis but psychogenic rheumatism, which they considered a psychoneurosis manifested by musculoskeletal complaints. They went on to state that primary fibrositis "puts its victims at the mercy of changes in external environment: thus weather, heat, cold, humidity, rest, exercise, etc. characteristically influences most of them for better or for worse." On the other hand, psychogenic rheumatism "puts its victims at the mercy of changes in the internal environment: thus their symptoms may vary with mood or psyche, pleasure, excitement, mental distraction, worry, or fatigue."

The description of psychogenic rheumatism included an attitude that was tense, anxious, defensive, and antagonistic. The chief symptoms were described as burning, tightness, weakness, numbness, tingling, or tired sensations that were often continuous day and night. They also describe severe fatigue causing disability, worsening of symptoms during and after exercise, and a "touch me not" reaction to examination. Psychotherapy was the preferred treatment approach for these patients. Patients with fibrositis, on the other hand, were treated with physical rehabilitation. In evaluating outcome, 82% of patients with primary fibrositis returned to duty, compared with only 64% of patients with psychogenic rheumatism.[12] In our current understanding, FM likely represents a combination of primary fibrositis and psychogenic rheumatism, with both conditions having a component of central pain amplification but diverging in the psychological and behavioral responses to pain.

Dr. Hugh Smythe provided the first modern description of widespread pain and tender points in the 1970s.[13] The term *fibromyalgia* was adopted soon thereafter because pathologic studies consistently fail to find evidence of inflammation in tender areas, calling into question the underlying hypothesis of the fibrositis construct. In 1981, Dr. Muhammad Yunus published a more comprehensive description of the symptoms and signs of FM,[14] which was recognized as a diagnosis by the American Medical Association in 1987. Yunus made the relevant comment that many patients with fibrositis syndrome, fibromyositis, fibromyalgia, myofibrositis, interstitial myofibrositis, myofascial pain syndrome, myofascitis, muscular rheumatism, nonarticular rheumatism, and tension rheumatism were also diagnosed with the separate entity of psychogenic rheumatism.

The American College of Rheumatology (ACR) published classification criteria in 1990 relying on the presence of widespread pain and tender points that allowed researchers to distinguish FM from other rheumatologic diseases and that had the effect of allowing researchers from around the world to identify a more homogenous group of patients for research.[15] A revision of the criteria published in 2010 eliminated tender points, placed less emphasis on widespread pain, and placed more emphasis on associated symptoms.[16] An additional modification to these criteria allow them to be used in epidemiologic studies.[17] Debate is ongoing regarding the most appropriate criteria for clinical and research uses, although in practice either these or other validated criteria sets will allow the clinician to make the diagnosis of FM.

Research intended to ascribe an etiology to FM began when Dr. Harvey Moldofsky reported abnormalities in polysomnographic studies of persons with FM in 1975, reporting intrusion of alpha or waking frequency waves in regions of delta or slow wave sleep now known to be nonspecific.[18] Since publication of the 1990 ACR classification criteria, investigators have identified a number of other potential mechanisms associated with FM that may be responsible for symptoms. In 2007, the U.S. Food and Drug Administration (FDA) approved pregabalin, an agent also approved for neuropathic pain, for treatment of FM. This step was followed by approval of the dual norepinephrine-serotonin reuptake inhibitors duloxetine and milnacipran for treatment of FM.[19]

Throughout the history of FM, controversy has existed regarding the veracity of patients' complaints and their reported impact on function.[8] The controversy has become somewhat contentious in the era of disability and the increased cost of FDA-approved medications. However, identifying FM and understanding the recent advances in mechanisms associated with development of central pain amplification has significant benefits that allow practitioners to educate patients about their symptoms and target pharmacologic and nonpharmacologic treatment to manage FM. With respect to the presence of psychogenic rheumatism in these patients, the most current approach to patients with FM who have excessive thoughts, feelings, and behaviors that are distressing and disruptive to daily life would be to consider an additional diagnosis of somatic symptom disorder, the new terminology in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5) that replaces somatization disorder, hypochondriasis, pain disorder, and undifferentiated somatoform disorder. This way of approaching patients separates the neurobiologic changes resulting in widespread pain amplification from the emotional and behavioral response to these symptoms. Considering both these aspects of FM, which occur in differing proportions in individual patients, may assist the practitioner in developing a treatment plan.

## DIAGNOSTIC CRITERIA

All of the validated criteria sets for FM include a requirement for chronic musculoskeletal pain. The ACR 1990 criteria focus on the widespread nature of the musculoskeletal pain, requiring that pain be present on both sides of the body, above and below the waist, and including the neck, back, or chest. A demonstration of the presence of widespread allodynia also was required, which was accomplished by a physical examination of 18 defined areas that should be painful with mechanical pressure, at a minimum of 11 sites (Table 52-1).[15] The so-called tender point examination has been controversial for several reasons, including differences in the ability to detect tenderness in men compared with women when using this examination. Another criticism of the ACR 1990 criteria is the absence of other important symptoms, such as fatigue and unrefreshing sleep.

In 2010, a new preliminary criteria set was published that eliminates the requirement for a physical examination, relying on the patient's report of the number of painful areas to define a widespread pain index and incorporating a symptom severity score in recognition of the other symptoms of FM (Table 52-2).[16] A person can be diagnosed with FM with pain being the dominant symptom or with a predominance of other somatic symptoms. The criticism of the 2010 criteria, as well as a modification published in 2011 intended for use in epidemiologic studies,[17] is the loss of the

**TABLE 52-1** American College of Rheumatology 1990 Criteria for the Classification of Fibromyalgia*

**1. History of Widespread Pain**

*Definition:* Pain is considered widespread when all of the following are present: pain in the left side of the body, pain in the right side of the body, pain above the waist, and pain below the waist. In addition, axial skeletal pain (cervical spine or anterior chest or thoracic spine or low back) must be present. In this definition, shoulder and buttock pain is considered as pain for each involved side. "Low back" pain is considered lower segment pain.

**2. Pain in 11 of 18 Tender Point Sites upon Digital Palpation**

*Definition:* Pain, upon digital palpation, must be present in at least 11 of the following 18 sites:

- Occiput: bilateral, at the suboccipital muscle insertions
- Low cervical: bilateral, at the anterior aspects of the intertransverse spaces at C5-C7
- Trapezius: bilateral, at the midpoint of the upper border
- Supraspinatus: bilateral, at origins, above the scapula spine near the medial border
- Second rib: bilateral, at the second costochondral junctions, just lateral to the junctions on upper surfaces
- Lateral epicondyle: bilateral, 2 cm distal to the epicondyles
- Gluteal: bilateral, in upper outer quadrants of buttocks in anterior fold of muscle
- Greater trochanter: bilateral, posterior to the trochanteric prominence
- Knee: bilateral, at the medial fat pad proximal to the joint line

Digital palpation should be performed with an approximate force of 4 kg.

For a tender point to be considered "positive," the subject must state that the palpation was painful. "Tender" is not to be considered "painful."

*For classification purposes, patients will be said to have fibromyalgia if both criteria are satisfied. Widespread pain must have been present for at least 3 months. The presence of a second clinical disorder does not exclude the diagnosis of fibromyalgia.

From Wolfe F, Smythe HA, Yunus MB, et al: The American College of Rheumatology 1990 Criteria for the Classification of Fibromyalgia. Report of the Multicenter Criteria Committee. *Arthritis Rheum* 33:160-172, 1990.

**TABLE 52-2** American College of Rheumatology 2010 Preliminary Diagnostic Criteria for Fibromyalgia

**Criteria**

A patient satisfies diagnostic criteria for fibromyalgia if the following three conditions are met:

1. WPI ≥7 and SSS ≥5 or
   WPI between 3 and 6 and SSS ≥9.
2. Symptoms have been present at a similar level for at least 3 months.
3. The patient does not have a disorder that would otherwise explain the pain.

**Ascertainment**

1. WPI: Note the number areas in which the patient has had pain during the past week. In how many areas has the patient had pain? Score will be between 0 and 19.

| | | | |
|---|---|---|---|
| Shoulder girdle, L | Hip (buttock, trochanter), L | Jaw, L | Upper back |
| Shoulder girdle, R | Hip (buttock, trochanter), R | Jaw, R | Lower back |
| Upper arm, L | Upper leg, L | Chest | Neck |
| Upper arm, R | Upper leg, R | Abdomen | |
| Lower arm, L | Lower leg, L | | |

2. SSS:
   Fatigue
   Waking unrefreshed
   Cognitive symptoms

*For the each of the three aforementioned symptoms, indicate the level of severity during the past week using the following scale:*

0 = No problem
1 = Slight or mild problems; generally mild or intermittent
2 = Moderate; considerable problems; often present and/or at a moderate level
3 = Severe: pervasive, continuous, life-disturbing problems

*Considering somatic symptoms* in general, indicate whether the patient has:*

0 = No symptoms
1 = Few symptoms
2 = A moderate number of symptoms
3 = A great deal of symptoms

The SSS is the sum of the severity of the three symptoms (fatigue, waking unrefreshed, and cognitive symptoms) plus the extent (severity) of somatic symptoms in general. The final score is between 0 and 12.

*For reference purposes, here is a list of somatic symptoms that might be considered: muscle pain, irritable bowel syndrome, fatigue/tiredness, thinking or remembering problem, muscle weakness, headache, pain/cramps in abdomen, numbness/tingling, dizziness, insomnia, depression, constipation, pain in upper abdomen, nausea, nervousness, chest pain, blurred vision, fever, diarrhea, dry mouth, itching, wheezing, Raynaud's phenomenon, hives/welts, ringing in ears, vomiting, heartburn, oral ulcers, loss/change in taste, seizures, dry eyes, shortness of breath, loss of appetite, rash, sun sensitivity, hearing difficulties, easy bruising, hair loss, frequent urination, painful urination, and bladder spasms.

L, Left; R, right; SSS, Symptom Severity Score; WPI, Widespread Pain Index.

From Wolfe F, Clauw DJ, Fitzcharles MA, et al. The American College of Rheumatology preliminary diagnostic criteria for fibromyalgia and measurement of symptom severity. *Arthritis Care Res* 62:600-610, 2010.

requirement that the pain be widespread (as defined in the 1990 criteria) and the potential expansion of the prevalence of FM by including persons with a lower level of pain symptoms, with a possible bias toward persons with somatic symptom disorder. Other criteria sets have been published that include other configurations of symptoms and signs, but the basic clinical manifestations remain unchanged.[20,21] At the present time, it remains unclear if the presence of tenderness, identified by tender point examination or other methods that demonstrate allodynia or hyperalgesia, improves the specificity of the diagnosis. It also is not clear how to best define widespread pain; for example, is a high number of painful sites regardless of their distribution the same as having pain all over the body? Although it is clear that symptoms not related to pain occur frequently and are important to patients with FM, the inclusion of patients whose clinical picture is dominated by nonpain symptoms, such as fatigue, unrefreshing sleep, and dyscognition, remains controversial.

## EPIDEMIOLOGY

A number of epidemiologic studies have been performed using different ways to identify patients with FM. The prevalence depends on the method of ascertainment. Using the ACR 1990 criteria, the worldwide prevalence is estimated at approximately 2% of the population. The first major study was conducted in Wichita, Kansas, using a population-based mail screening followed by physician assessment.[22] In that study, the overall prevalence was 2%, with 3.4% of women and 0.5% of men diagnosed with FM. Subsequently, the prevalence in London, Ontario, Canada, was found to be 4.9% of women and 1.6% of men.[23] It is of interest that these same Canadian investigators evaluated an Amish community to determine if litigation or compensation availability had an influence on FM prevalence.[24] They found that the age-adjusted point prevalence of FM was 10.4% in women and 3.7% in men, which was greater than that found in rural or nonrural non-Amish adults and was interpreted as providing evidence that FM is present in communities that lack a financial incentive for having the disorder.

In France, also using a two-step method of ascertainment, the prevalence was 1.6%; gender was not specified.[25] In a Korean hospital study, the prevalence was 1.7%, with 3.2% of females and 0.6% of males being affected.[26] The prevalence of FM appears to increase with age to about age 70 years, after which it decreases slightly.[22,23] FM can be diagnosed in children—usually in adolescents, and more commonly in girls.[27] The prevalence in patients with rheumatic diseases is estimated at 11% to 30%, although a recent large study suggests that the range is between 6% and 13% for the most common rheumatologic conditions.[28]

When using a modified version of the ACR 2010 criteria developed for use in population studies and without physician examination, the prevalence in Olmstead County, Minnesota, was 6.4%: 7.71% in women and 4.48% in men.[29] A German study using these same criteria reported a prevalence of 2.1% overall, with 2.4% in women and 1.8% in men.[30] An internet survey in Japan also using the modified 2010 criteria reported an overall prevalence of 2.1%, with 2.3% in women and 0.85% in men.[31]

The prevalence of FM is generally greater in clinical settings than in epidemiologic studies. It was noted to be 5.7% in general medical clinics[32] and 2.1% in family practice settings.[33] In rheumatology clinics, FM prevalence was higher, with between 12% and 20% of new patients having this diagnosis.[14,34] The prevalence of FM in children is approximately 1.5% across studies, and it is usually diagnosed in adolescent girls.[27,35]

The incidence of FM is not easily determined; however, one study using an *International Classification of Diseases, Ninth Revision* (ICD-9) coding insurance claims database containing 62,000 nationwide enrollees per year between 1997 and 2002 found an age-adjusted incidence of 11.28 per 1000 person years for females and 6.88 cases per 1000 person-years in males.[36] In that study, patients with FM were between two and seven times more likely to have comorbid depression, anxiety, headache, irritable bowel syndrome, chronic fatigue syndrome, systemic lupus erythematosus, and rheumatoid arthritis. Contrast these data with the incidence of FM in patients with other rheumatic diseases: In a cohort of approximately 1000 patients in the early stage of arthritis who were followed up by rheumatologists, the incidence of FM was 6.77 per 100 person-years in the first year after the diagnosis. The incidence declined to 3.58 per 100 person-years in the second year.[37] This makes FM approximately 10-fold more common in patients with early arthritis than in a general claims dataset.

## CLINICAL FEATURES

In clinical settings, patients often report that they have pain "all over their body." They often have difficulty precisely localizing the pain and may describe it as moving from place to place. Patients often describe the pain as "deep," originating in muscles or bones. Patients may use many different pain descriptors, including "throbbing," "stabbing," and "burning." In a study comparing 100 patients who had FM and met 1990 ACR criteria with 76 control subjects who had widespread pain, four symptoms distinguished patients with FM from control subjects: pain severity, severe fatigue lasting 24 hours after minimal activity, weakness, and self-reported swelling of the neck glands.[38] Pain is typically present on most days almost all day, although the intensity may wax and wane. Patients often describe tenderness to light touch or pressure. Pain is typically exacerbated by physical activity, and some patients report that it is worsened with changes in the weather, although this phenomenon has not been confirmed in rigorous studies. In addition to pain, patients report muscular stiffness, tightness, and weakness.

The main purpose of the physical examination is to evaluate the patient for other conditions that cause musculoskeletal pain. Patients with FM exhibit tenderness that can be identified by tender point examination. Tender point sites represent specific areas of muscle, tendon, and fat pads that are more tender to palpation than surrounding sites. Sites selected as part of the ACR 1990 criteria represent tender point sites that best discriminated between patients with and without FM. To test for pain with digital palpation, the ACR 1990 criteria indicate that the examiner should press with an approximate force of 4 kg.[15] The patient should report pain in response to this level of pressure,

which in practice is approximately the force it takes for the thumbnail to blanche.

In addition to the usual musculoskeletal and connective tissue examination, it is useful to evaluate patients, particularly young patients, for joint hypermobility.[39] There are indications that FM may be more common among patients with these findings, and physical measures may be quite useful in management of patients with these associations. If regional pain disorders, such as bursitis, tendonitis, or arthritis, can be identified during the physical examination, treatment of these potentially exacerbating pain generators may help with the more widespread pain. Certainly, any mechanical or inflammatory conditions with the potential to cause musculoskeletal pain should be identified and treated.

The pain of FM is often accompanied by other pain amplification syndromes (Table 52-3). These syndromes often have been present for many years and, as with FM, they may wax and wane over time. It may be important for the patient to understand the genetic and physiologic relationships between these diagnoses. In addition, it is clinically important to determine which symptoms have the greatest impact on the patient. Symptom domains have been evaluated by patient and physician Delphi exercises and were generally concordant (Table 52-4).[40] Assessing these clinical concerns may help the clinician prioritize management strategies. For example, if sleep is a major contributor to symptoms, the patient may be counseled on sleep hygiene or, if appropriate, screened for restless leg syndrome or sleep apnea and then referred for evaluation and management of sleep disorder.[41] Similarly, if depression or anxiety is a major contributor to the overall symptom complex, then attention should be given to management of these concerns.[42] Dyscognition may be of major importance to patients, particularly in the workplace.[43,44] These complaints have validity when studied carefully, with abnormalities in executive function and divided attention. Fatigue may be the most difficult symptom to evaluate and treat because it may be due to deconditioning, depression, disrupted sleep, medication adverse effects, or comorbid conditions.

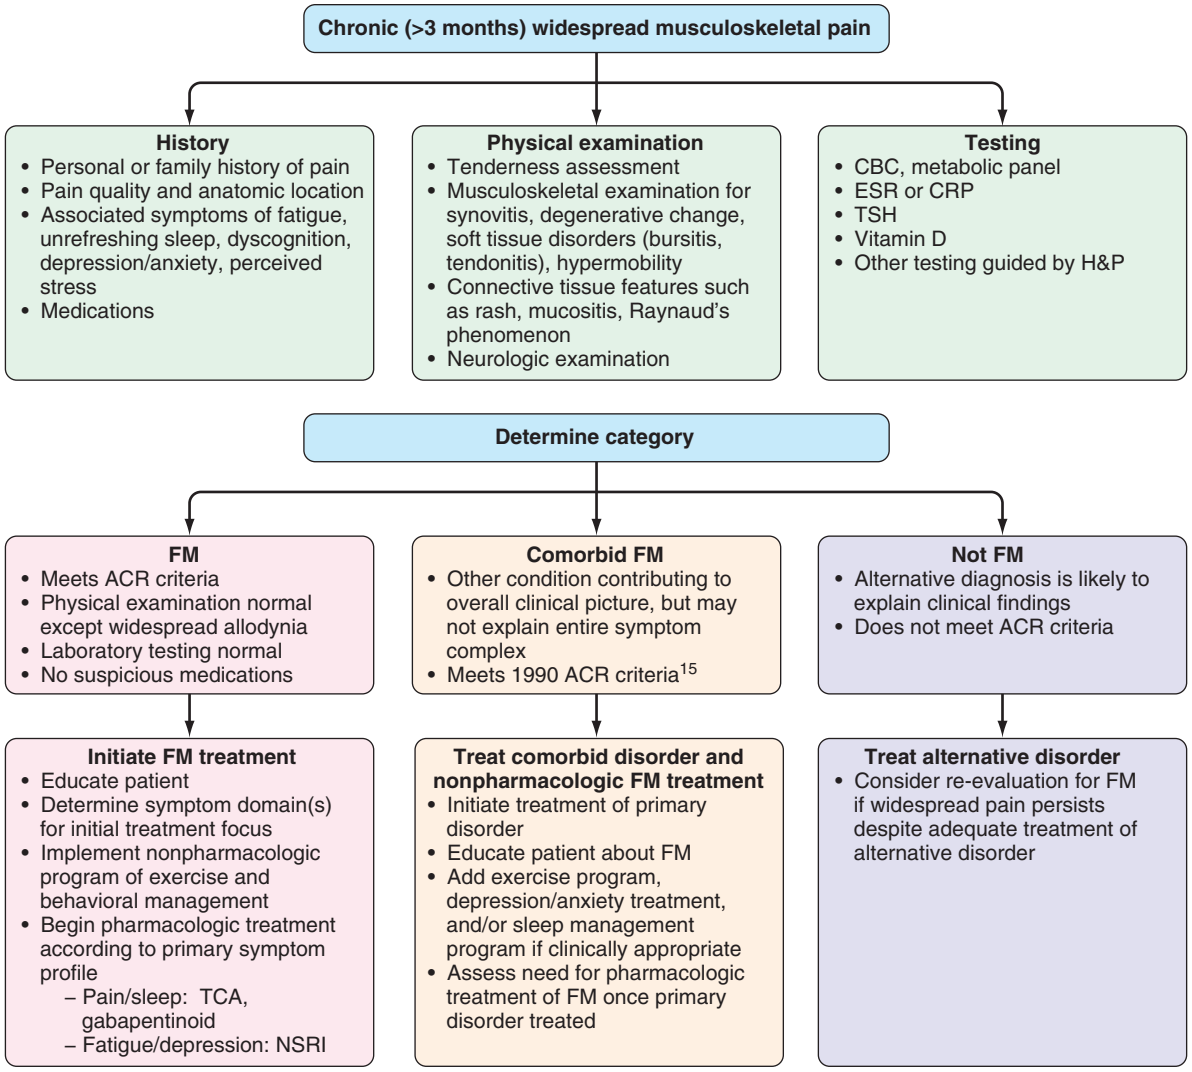

**Figure 52-1** Strategy for evaluation and initial management of patients with chronic widespread musculoskeletal pain. After initial evaluation, patients may be diagnosed with fibromyalgia (FM), FM comorbid with another diagnosis, or not FM. Strategies for initial management of each category are shown. ACR, American College of Rheumatology; CBC, complete blood cell count; CRP, C-reactive protein; ESR, erythrocyte sedimentation rate; H&P, history and physical examination; NSRI, norepinephrine serotonin reuptake inhibitor; TCA, tricyclic anti-depressants; TSH, thyroid-stimulating hormone.

## DIFFERENTIAL DIAGNOSIS AND RHEUMATOLOGIC COMORBIDITIES

A strategy for diagnosing FM is shown in Figure 52-1.[45,46] Common conditions that should be considered in the differential diagnosis are shown in Table 52-5. Most of these conditions should be identified by careful history and physical examination with selected laboratory tests. Medications that may be associated with FM mimics, such as statins, should be noted. Physical findings that should prompt additional testing include prominent focal abnormalities on neurologic examination, such as weakness or numbness, joint inflammation, fever, rash, skin ulcers, or alopecia.[45] Hypothyroidism can be excluded using laboratory tests. Seronegative spondyloarthropathies may have elevated inflammatory markers and abnormal results of imaging studies. These patients also typically report that their pain improves rather than worsens with exercise. In older patients, polymyalgia rheumatic should be excluded using laboratory testing. Screening questions for major depressive disorder should be undertaken. If the history and physical examination suggest inflammatory arthritis or a systemic autoimmune disease, appropriate laboratory and serologic testing should be undertaken. It is not useful to perform repeat diagnostic testing, particularly if symptoms have been present for more than 1 to 2 years and if the symptoms do not change.

FM is frequently comorbid with other rheumatologic diseases. In a recent study of 835 patients, the prevalence of FM was 13.4% in 67 patients with systemic lupus erythematosus, 12.6% in 119 patients with ankylosing spondylitis, 12% in 25 patients with Sjögren's syndrome, 10.1% in 238 patients with osteoarthritis, 6.9% in 29 patients with polymyalgia rheumatica, and 6.6% in 197 patients with rheumatoid arthritis. Significant correlations were found between disease activity indexes and Fibromyalgia Impact

*Recommended routine testing includes ESR or CRP and thyroid-stimulating hormone. Other diagnostic testing should be guided by risk profile and history and physical examination. Repeated diagnostic testing is discouraged.

CRP, C-reactive protein; ESR, erythrocyte sedimentation rate.

Questionnaire (FIQ) scores for most rheumatologic patients.[28] Identifying central pain amplification has important implications for evaluation and treatment of comorbid conditions. For example, it is well known that the tender joint component and patient-reported symptoms of the Disease Activity Score (DAS)-28 are higher in patients with FM than in patients without FM. Using more objective criteria for synovitis in those patients, such as ultrasound, may be required to determine if treatment of rheumatoid arthritis should be accelerated.

Other comorbidities are frequent in patients with FM and do not vary a great deal with the clinical site in which the patient is seen. Patients with FM have a significantly higher prevalence of visceral pain syndromes, regional pain syndromes, and mood disorders. In one study using an ICD-9 coding insurance claims database containing 62,000 nationwide enrollees, patients with FM were between two and seven times more likely to have comorbid depression, anxiety, headache, irritable bowel syndrome, chronic fatigue syndrome, systemic lupus erythematosus, and rheumatoid arthritis.[36] In a study from the United Kingdom primary care dataset of persons eventually diagnosed with FM, visit rates were highest for depression, fatigue, chest pain, headache, and sleep disturbance.[47] A population-based study from the Swedish Twin Registry evaluating 44,897 persons found substantial co-occurrence for chronic widespread pain with chronic fatigue (odds ratio [OR], 23.53; 95% confidence interval [CI], 19.67 to 18.16), depressive symptoms (OR, 5.26; 95% CI, 4.75 to 5.82), and irritable bowel syndrome (OR, 5.17; 95% CI, 4.55 to 5.88).[48] Using a co-twin analysis, the associations remained for chronic fatigue and irritable syndrome but not for depressive symptoms. In a rheumatology practice, patients with FM were found to have high lifetime rates of migraine, irritable bowel syndrome, chronic fatigue syndrome, major depression, and panic disorder.[49]

FM is frequently identified in patients seen primarily for interstitial cystitis, irritable bowel syndrome, migraine and other forms of headache, temporomandibular disorder, multiple chemical sensitivities, and chronic fatigue syndrome. In a systematic review from 2001 of the aforementioned conditions, it was noted that there were many similarities in case definition and symptoms and that the proportion of patients with an unexplained clinical condition meeting criteria for a second unexplained condition was striking.[50] Psychiatric conditions associated with FM include major depressive disorder, bipolar disorder, anxiety disorders, including panic disorder, post-traumatic stress disorder, social phobia and obsessive compulsive disorder, and substance abuse disorder.[51,52] In a study of 108 persons with FM and 228 persons without FM, the odds ratio for persons with FM having bipolar disorder was 153 (95% CI, 26 to 902; $P$ <0.001); any anxiety disorder, 6.7 (95% CI, 2.3 to 20; $P$ <0.001); substance use disorder, 3.3 (95% CI, 1.1 to 10; $P$ = 0.040); and major depressive disorder, 2.7 (95% CI, 1.2 to 6.0; $P$ = 0.13).[51]

Should a patient with FM have multiple pain amplification disorders, the practitioner will need to determine if he or she should be treated as having one disorder of central etiology or whether there is a clinical reason for diagnosis of multiple different disorders. Many of the medications and nonpharmacologic treatments for these conditions overlap. To avoid use of multiple medications, if a single agent can be used—for example, an agent with anti-depressant activity—it may be possible to treat comorbidities and FM.

## ASSESSMENT OF SEVERITY

Symptom severity, physical function, and disability are key status and outcome variables in persons with FM. In the clinic, numeric ratings for pain and fatigue along with a measure of functional status, including those routinely used for rheumatic diseases, such as one of the Health Assessment Questionnaires (HAQ) instruments, work very well in patients with FM.[53,54] The revised FIQ (FIQ-R) addresses all of these core domains, as well as FM impact and several

**The revised Fibromyalgia Impact Questionnaire**

**Domain 1 directions:** For each of the following nine questions, check the one box that best indicates how much your fibromyalgia made it difficult to do each of the following activities over the past 7 days:

| | | | |
|---|---|---|---|
| Brush or comb your hair | No difficulty | □ □ □ □ □ □ □ □ □ □ □ | Very difficult |
| Walk continuously for 20 minutes | No difficulty | □ □ □ □ □ □ □ □ □ □ □ | Very difficult |
| Prepare a homemade meal | No difficulty | □ □ □ □ □ □ □ □ □ □ □ | Very difficult |
| Vacuum, scrub, or sweep floors | No difficulty | □ □ □ □ □ □ □ □ □ □ □ | Very difficult |
| Lift and carry a bag full of groceries | No difficulty | □ □ □ □ □ □ □ □ □ □ □ | Very difficult |
| Climb one flight of stairs | No difficulty | □ □ □ □ □ □ □ □ □ □ □ | Very difficult |
| Change bed sheets | No difficulty | □ □ □ □ □ □ □ □ □ □ □ | Very difficult |
| Sit in a chair for 45 minutes | No difficulty | □ □ □ □ □ □ □ □ □ □ □ | Very difficult |
| Go shopping for groceries | No difficulty | □ □ □ □ □ □ □ □ □ □ □ | Very difficult |

**Domain 2 directions:** For each of the following two questions, check the one box that best describes the overall impact of your fibromyalgia over the past 7 days:

| | | | |
|---|---|---|---|
| Fibromyalgia prevented me from accomplishing goals for the week | Never | □ □ □ □ □ □ □ □ □ □ □ | Always |
| I was completely overwhelmed by my fibromyalgia symptoms | Never | □ □ □ □ □ □ □ □ □ □ □ | Always |

**Domain 3 directions:** For each of the following 10 questions, check the one box that best indicates the intensity of your fibromyalgia symptoms over the past 7 days:

| | | | |
|---|---|---|---|
| Please rate your level of pain | No pain | □ □ □ □ □ □ □ □ □ □ □ | Unbearable pain |
| Please rate your level of energy | Lots of energy | □ □ □ □ □ □ □ □ □ □ □ | No energy |
| Please rate your level of stiffness | No stiffness | □ □ □ □ □ □ □ □ □ □ □ | Severe stiffness |
| Please rate the quality of your sleep | Awoke rested | □ □ □ □ □ □ □ □ □ □ □ | Awoke very tired |
| Please rate your level of depression | No depression | □ □ □ □ □ □ □ □ □ □ □ | Very depressed |
| Please rate your level of memory problems | Good memory | □ □ □ □ □ □ □ □ □ □ □ | Very poor memory |
| Please rate your level of anxiety | Not anxious | □ □ □ □ □ □ □ □ □ □ □ | Very anxious |
| Please rate your level of tenderness to touch | No tenderness | □ □ □ □ □ □ □ □ □ □ □ | Very tender |
| Please rate your level of balance problems | No imbalance | □ □ □ □ □ □ □ □ □ □ □ | Severe imbalance |
| Please rate your level of sensitivity to loud noises, bright lights, odors, and cold | No sensitivity | □ □ □ □ □ □ □ □ □ □ □ | Extreme sensitivity |

**Scoring: Step 1.** Sum the scores for each of the three domains (function, overall, and symptoms).
**Step 2.** Divide domain 1 score by three, divide domain 2 score by one (that is, it is unchanged), and divide domain score 3 by two.
**Step 3.** Add the three resulting domain scores to obtain the total revised Fibromyalgia Impact Questionnaire score.

**Figure 52-2** The revised Fibromyalgia Impact Questionnaire (FIQR) assesses functional status as well as the overall impact and fibromyalgia symptoms.[55] The FIQR total score can be used as an outcome measure in clinical studies. The FIQR function score and the symptom scores can be used individually to determine severity. Paper and online versions perform similarly, and the FIQR performs similarly to the original version.

other symptoms (Figure 52-2).[55] The ACR 2010 criteria modified for epidemiologic studies provide another measure of FM severity; it is called the FM Symptom Scale and combines the Widespread Pain Index (WPI) and the modified Symptom Severity Score (SSS) into a continuous score.[16]

For research purposes, the Outcome Measures in Rheumatoid Arthritis Clinical Trials (OMERACT) FM working group has recommended that the domains of pain, fatigue, sleep, depression, physical function, quality of life, multidimensional function, patient's global impression of change, tenderness, dyscognition, anxiety, and stiffness be assessed.[56] This assessment can be accomplished using the FIQ-R and the Medical Outcomes Scale SF-36.[57]

## MECHANISMS

The two intrinsic mechanisms associated with the risk of developing chronic painful musculoskeletal disorders, including FM, are pain amplification and psychological distress.[5] Pain amplification may be related to sensitization of afferent pathways in the peripheral or central nervous system that process coded pain information or impairment in the inhibitory systems of the central nervous system.[9] Psychological factors include enhanced somatic awareness or the perception and interpretation of sensory information, anxiety, depression, perceived stress, and catastrophizing.[58] It is likely that genetic vulnerability coupled with environmental triggers are required to produce the clinical phenotype. The specific environmental triggers may include nonspecific behavioral factors, such as smoking and obesity, stress exposures, and nociceptive musculoskeletal pain. The combination of risk factors is likely to vary among persons who meet the definition of FM.

### Genetic Risk

A number of studies have demonstrated the importance of genetics in the susceptibility of FM and other syndromes that are often comorbid with FM. A study of familial aggregation reported that first-degree relatives of FM probands are far more likely to have FM (OR, 8.5; 95% CI,

2.8 to 26; $P$ <0.001). Twin studies have estimated that the contribution of genetic factors to chronic widespread musculoskeletal pain load on two latent traits are best explained by both affective and sensory components.[59] These twin studies suggest a modest genetic influence with concordance for chronic widespread pain, with concordance for monozygotic female twins of 30%, and for dizygotic female twins of 16%.[60]

It is unlikely that a specific gene or set of genes is associated with FM. Rather, similar to autoimmune diseases, there are more general vulnerability genes that interact with environmental exposures to lead to clinical expression of pain conditions. Thus most of the genes associated with FM have also been reported in association with other clinically defined pain syndromes. For example, two major neurotransmitter pathways have been repeatedly associated with musculoskeletal pain.[5] The first is the adrenergic pathway, in which *COMT*, the gene encoding the enzyme catechol-*O*-methyltransferase that is responsible for the catabolism of catechol neurotransmitters, such as epinephrine, norepinephrine, and dopamine, is most frequently associated with chronic musculoskeletal pain conditions. Most studies of *COMT* report an increased risk of chronic pain associated with a Val159Met (rs4680) that encodes a protein with lower enzymatic activity.[5] More extensive studies have expanded the functional locus to three major haplotypes that modify expression and activity of the enzyme, thus conferring low-risk and high-risk phenotypes for acute pain sensitivity, as well as risk for developing chronic pain.[61] Additional genetic variation in the β2-adrenergic receptor gene (*ADRB2*; rs1042713 and rs1042714) has been associated with an increased risk of FM and chronic widespread pain. Haplotype variants that regulate β2-adrenergic receptor expression and internalization are associated with differences in susceptibility to chronic pain.[62]

The second pathway associated with chronic pain syndromes is the serotonin pathway. Specific genes include the 5-hydroxytryptamin receptor 2A (*HTR2A*) and 5HT transporter (*SLC6A4*).[63-65] A 44–base pair insertion/deletion polymorphism in the promoter region of *SLC6A4* is most frequently associated with risk of chronic pain conditions, including FM.[5]

Both of these genetic pathways are also associated with several "endophenotypes" or intermediate measurable phenotypes that are present in patients with FM. These endophenotypes include autonomic dysregulation, altered pain processing and modulation, sleep dysfunction, and anxiety, in the case of the adrenergic pathway.[5] Personality and affective traits, such as somatic awareness, depression, and anxiety, have been associated with genetic variation in the serotonin pathway and are associated with risk for chronic pain.[5]

Candidate gene analysis of patients carrying the diagnosis of FM identified pathways also including genes within the biogenic amine and adrenergic pathways though different from candidates more generally associated with chronic pain, as well as a cannabinoid receptor.[6] A genome-wide linkage scan study of families with FM identified chromosome 17p11.2-q11.2, a region that contains the serotonin transporter gene (*SLC6A4*) and the transient receptor potential vanilloid channel 2 gene (*TRPV2*).[66]

## Central Pain Amplification and Potential Peripheral Mechanisms

Several lines of evidence support the concept of central pain amplification (also called central sensitization), which is generally interpreted as a change in the relationship between stimulus intensity and the perception of the stimulus as noxious or painful.[67] In patients with FM, stimuli usually perceived as innocuous are perceived as painful (allodynia), and painful stimuli are given a higher pain rating (hyperalgesia).[68] During central sensitization, second-order and higher-order neurons exhibit transcriptional and translational events that lead to heightened sensitivity.

Most of the data supporting central sensitization are generated through psychophysical testing using different types of stimuli such as pressure or heat. The investigator may use either a subjective report of pain or an objective measure such as brain imaging. One experimental paradigm called wind-up or temporal summation of pain measures the change in pain intensity after repeated applications of a sensory stimulus.[68] Healthy persons will experience an increase in pain in response to identical stimulus intensity if the stimulus is presented with a short interstimulus interval. Patients with FM report the same wind-up phenomenon with longer interstimulus intervals, which is interpreted to mean that patients with FM have presensitized pain transmission neurons.[69,70] Patients with FM also have a delayed recovery to baseline, termed *aftersensations*, which correlates with clinical pain intensity.[70]

Studies have also implicated a deficiency in descending inhibitory control of noxious stimulation in persons with FM. Normally, endogenous inhibitory mechanisms are activated in response to nociceptive stimuli and involve serotonergic, noradrenergic, and opioidergic inhibitory pathways. Persons with FM do exhibit reduction in these pathways.[71] It is difficult to know whether activation of afferent pain pathways, deficiency of descending pathways, or both explain enhanced pain perception in a given person. Positron emission tomographic scanning has demonstrated alterations in mu-opioid receptor availability and increased dopamine activity in persons with FM, both of which could indicate alteration of normal pain inhibitory pathways.[72,73]

Disagreement exists regarding the role of peripheral nociceptive input in the cause and maintenance of FM, although the increased prevalence of FM in persons with other rheumatic diseases provides an argument that persistent peripheral pain generators may be an important risk factor contributing to the phenotypic changes in pain transmission neurons.[74] Other triggering events, such as certain types of infections, trauma, or psychological stress, have been proposed.[75,76] Pain is localized to muscle tissues in virtually all persons with FM. Abnormalities in muscle tissues have been reported, including altered metabolisms by phosphorus-31 magnetic resonance spectroscopy (MRS).[77] Some data implicate muscle microcirculation and muscle mitochondria in FM.[68,78,79] Reports have been made of small fiber neuropathies in persons with FM, which are thought potentially to be a source of persistent nociceptive input.[80-83] For example, in a recent study of persons with FM and control subjects, intraepidermal nerve fiber

density was reduced in 32.6% in the former.[80] Another study used microneurography to record C-fiber action potentials in persons with FM and control subjects.[83] Persons diagnosed with FM had abnormalities in the functioning of type 1B C nociceptors that are normally silent and mechanoinsensitive, including spontaneous activity, prolonged firing in response to mechanical stimulation, and/or a distinctive pattern of activity-dependent slowing of conduction velocity. Whether these data indicate that a subset of persons with FM may in fact have neuropathic pain associated with a non–length-dependent small fiber neuropathy or whether the key element that results in FM is that peripheral pain generators lead to central sensitization is not clear.

Altered peripheral and cerebrospinal fluid levels of neurotrophins, chemokines, and cytokines have been reported in persons with FM.[68] Mechanisms for the effects of these substances in explaining the pathophysiology of FM remain undetermined. However, the concept that activation of glial cells by cytokines and chemokines may accompany activation of pain transmission neurons can be demonstrated in animal models.[84]

Functional neuroimaging has contributed much to the understanding of FM and, because the outcome is objective, it has clearly confirmed the validity of patient reports. One of the first studies to address this issue demonstrated that greater regional cerebral blood flow receiving pain pathway input was related to the patient's report of pain rather than to the stimulus intensity.[85] Other neuroimaging techniques have emerged and have provided information in FM and other chronic pain states. Using proton MRS ($^{1}$H-MRS), persons with FM were found to have low levels of *N*-acetyl-aspartate, a metabolite believed to be a marker of neuronal density and viability, perhaps indicating loss of neural function and activity in the hippocampus.[86] Also using $^{1}$H-MRS, it was found that the main excitatory neurotransmitter, glutamate/glutamine, was elevated in the posterior insular cortex, and a decrease in the signal correlated with improvements in pain.[87,88] Other brain regions of persons with FM, including the amygdala, posterior cingulate, and ventral lateral prefrontal cortex, had elevated levels of glutamate/glutamine, suggesting a possible role for this neurotransmitter in pain and perhaps other symptoms of FM.[86]

### Stress Response Systems

A number of studies suggest abnormalities of stress-response systems—the hypothalamic-pituitary-adrenal (HPA) axis and autonomic nervous system—in persons with FM. It is unclear whether these abnormalities are a cause or a consequence of FM. Genetic studies implicating genes in these pathways suggest that lack of resiliency in these pathways may provide a measure of vulnerability, but other studies implicate exposure to acute or chronic stress as a triggering mechanism. One study of patients without chronic widespread pain but who were at risk based on high rates of psychological distress and somatization provided evidence that HPA axis dysfunction may precede the development of chronic pain[89] and that HPA axis dysfunction was associated with the subsequent development of chronic widespread pain.[90] There is a striking lack of consistency in the specific HPA axis measures associated with FM.[91]

Many studies, however, consistently demonstrate alterations of measures of autonomic function, especially heart rate variability. These alterations are most often said to demonstrate predominance of the sympathetic nervous system, a characteristic shared by other pain amplification syndromes.[92] Other studies are interpreted as demonstrating stronger parasympathetic decline, a finding associated with the tendency to exhibit defensive behaviors.[93]

## SOCIAL AND PSYCHOLOGICAL FACTORS

### Life Stress and Socioeconomic Factors

In many longitudinal epidemiologic studies, chronic pain and other somatic symptoms can be predicted by childhood abuse and traumas, low educational attainment, social isolation, depression, and anxiety.[94] In a population-based study to determine psychosocial factors that predicted new-onset chronic widespread pain, investigators identified a random sample of subjects from sociodemographically disparate backgrounds and then identified more than 3000 who did not have pain at baseline and more than 300 who had new widespread musculoskeletal pain at follow-up.[95] The strongest predictors were premorbid somatic symptoms, illness behaviors, and sleep problems. In another community-based study, perceived physical and emotional trauma as precipitating factors for FM were associated with health care seeking rather than pain severity.[96]

Lower socioeconomic status predicts greater symptom severity and functional impairment in persons with FM, even controlling for levels of pain, depression, and anxiety.[97] The biopsychosocial model of pain posits that pain experience and its impact on the individual is a function of interacting combinations of nociceptive input; psychological processes, including beliefs; coping repertoire; and mood; and environmental contingencies that would include family, community, and cultural rules or expectations.[98] All of these factors are likely to play a key role in the clinical expression and health impact of FM.

### Personality, Cognitive, and Psychological Factors

Persons with FM may have a specific personality profile characterized, for example, by high levels of neuroticism. However, many studies include state variables, such as catastrophizing, self-esteem, and motivation or coping strategies, with personality traits. It is sometimes unclear whether a personality feature is a state or a trait; for example, catastrophizing may be seen as a personality feature, a cognitive error, or a coping strategy.[99] A recent study using a standard five-factor personality scale (neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness) showed that patients with FM were not different from patients with other rheumatic pain conditions or other chronic illnesses.[100] Furthermore, the scores fell within the normal range for the general population. However, a cluster of patients with FM was identified with a personality profile (high neuroticism and lower extraversion) that reflects a proneness to experience emotional distress, a difficulty for

positive emotion, and a tendency to ineffective use of emotional regulation processes rather exhibiting rumination and maladaptive behaviors. The patients in this cluster also exhibited more psychosocial problems.[100]

Another way of stratifying patients is the psychological and behavioral response to chronic pain. Persons with FM have been characterized and divided into groups that predict outcome based on psychological characteristics.[101] Persons classified as "dysfunctional" exhibit the highest pain intensity, interference, and distress and the lowest control and activity levels. The "adaptive coper" groups report the lowest levels of pain and interference, as well as the highest activity levels. The "interpersonally distressed" patients report high levels of affective distress and more negative spousal responses to pain.

It is likely that important relationships exist between psychological and physiologic pathways in persons with FM. This likelihood is certainly not surprising because regulation of domains characterized as psychological and physiologic use common mediators. For example, in a recent study of persons with FM, investigators performed a cluster analysis based on pain characteristics and cognitive, affective, and behavioral responses to pain and stress.[102] The study demonstrated that psychophysiologic responses of blood pressure, heart rate, and skin conductance were associated with specific types of psychological coping and psychiatric diagnoses.[103]

## TREATMENT APPROACHES

### Education and Self-Management

Treatment guidelines for persons with FM typically emphasize the need to incorporate principles of self-management.[104,105] Making the diagnosis of FM provides an intellectual framework for educating patients about their symptoms and engaging them as an active participant in the treatment plan (Figure 52-3).[105] Providing the diagnosis can provide relief from health-related anxiety, and no studies have suggested that labeling with FM is harmful for health or health care expenditures.[106,107] Educating patients regarding the physiology of chronic pain in FM, as well as the importance of nonpharmacologic therapies for its management, is likely to be beneficial. One key goal is to assist the patient in differentiating peripheral pain generators from the centrally maintained diffuse pain. In addition, educating patients about which treatment is intended to target which pain symptom may help with adherence and satisfaction with treatment. For example, nonsteroidal anti-inflammatory drugs (NSAIDs) or disease-modifying agents may be intended for peripheral mechanical or inflammatory pain but would not be expected to effectively treat FM pain.[104]

A comparison of network meta-analyses of different treatment strategies found that multicomponent therapies incorporating pharmacologic therapies with aerobic exercise

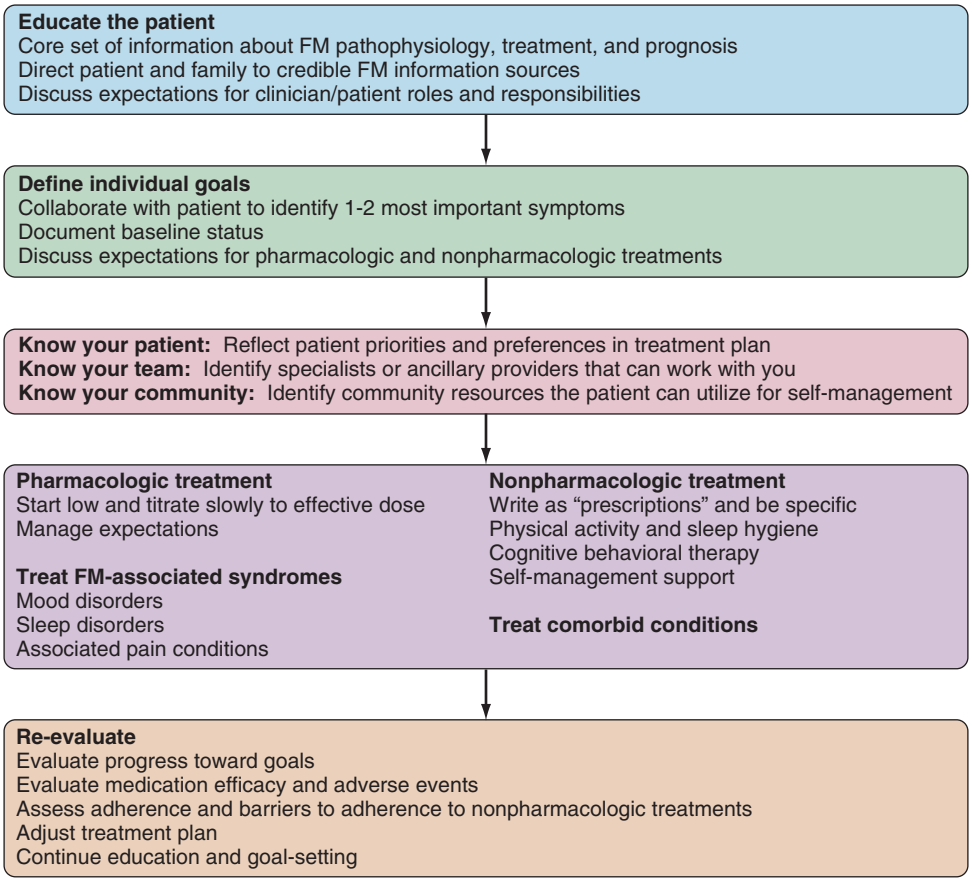

**Figure 52-3** Integrated approach to fibromyalgia (FM) management. *(Modified from Arnold LM, Clauw DJ, Dunegan LJ, et al: A framework for fibromyalgia management for primary care providers.* Mayo Clinic Proceedings. *87[5]:488–96, 2012.)*

and cognitive behavioral therapy (CBT) seems most promising.[108] Many of the nonpharmacologic strategies useful for FM may not be available locally but lend themselves to Internet-based programs or written materials.[105] The provider and patient should collaborate to prioritize individual treatment goals and develop a plan to achieve those goals. Focusing on longer term goals, while acknowledging that FM symptoms tend to wax and wane in response to both external and internal environmental stressors, is advised.[105]

## Exercise and Body-Based Therapies

A number of systematic reviews have been conducted to assess the benefits of exercise for persons with FM.[109-112] In evaluating exercise interventions, a recent umbrella systematic review synthesized physical activity interventions for adults with FM, focusing on four outcomes, including pain, multidimensional function, physical function, and adverse effects.[113] The researchers found positive results of diverse exercise interventions for all outcomes and no adverse effects. The variability of the interventions did not allow for recommendations regarding the mode of exercise or the frequency, intensity, and duration of treatments. It is not possible to rigorously determine whether land- or water-based exercise is superior. All major outcomes, including function, pain, stiffness, muscle strength, and fitness, improved after aquatic exercise training compared with control subjects, although the quality of the evidence was rated as low to moderate; however, land-based training was superior to aquatic training for improving muscle strength.[112] Tai chi, yoga, qigong, and a variety of other movement therapies have also been reported to be safe and effective for overall symptoms and physical functioning in persons with FM.[114] In general, active physical exercise strategies of any type will be helpful. Finding the exercise to which the patient is most likely to adhere will be the most important factor.

More passive strategies may be useful as an adjunct but should not replace active physical exercise. A meta-analysis of balneotherapy and hydrotherapy reported evidence for a small reduction in pain and a small improvement in health related to quality of life, although the investigators recommend that high-quality studies with larger sample sizes be performed.[115] A recent systematic review of massage suggested moderate evidence that myofascial release is beneficial for FM symptoms, but only limited evidence supports the application of connective tissue massage and Shiatsu. Swedish massage did not improve outcomes.[116] Acupuncture has been compared with sham acupuncture, and a meta-analysis including nine trials concluded that there was not enough evidence to prove the efficacy of acupuncture therapy compared with sham acupuncture.[117] Neurostimulatory therapies, including transcutaneous electrical nerve stimulation and central neurostimulatory therapies, may be helpful in persons with FM.[118,119]

## Cognitive Behavioral Therapy

CBT includes interventions that are based on the basic premise that chronic pain is maintained by cognitive and behavioral factors and that psychological treatment leads to changes in these factors through training in specific techniques.[120] These interventions would include cognitive restructuring and behavioral training, such as relaxation and social skills training. CBT provides benefit for reducing pain, negative mood, and disability in patients with FM.[121] CBT is typically delivered in group therapy over variable periods. Mindfulness-based stress reduction is a cognitive therapy that helps persons self-manage and reframe worrisome and intrusive thoughts through mindfulness meditation. This technique reduced perceived stress, sleep disturbance, and symptom severity, although there was no improvement in pain or physical functioning in a randomized, controlled clinical trial.[122] Operant behavioral treatment focuses on the modification of pain behavior by increasing activity levels, reducing health care–seeking behavior, and reducing pain-reinforcing behaviors in significant relationships.[120] Overall, the magnitude of benefit for CBT is small across the symptom domains of FM, with pain coping, depressed mood, and health care–seeking behavior having the most significant improvement.

## Pharmacologic Approaches

The major classes of drugs useful for patients with FM are anti-depressants, particularly those with mixed reuptake inhibition of serotonin and norepinephrine, such as duloxetine and milnacipran, and other agents useful for neuropathic pain, such as gabapentin and pregabalin (Table 52-6).[104] Evidence-based guidelines have been formulated by the American Pain Society (2005),[123] the European League Against Rheumatism (2007),[124] the Association of the Scientific Medical Societies in Germany (2008),[125] the Canadian National Fibromyalgia Guideline Advisory Panel (2012),[104] and the Israeli Rheumatology Association (2013).[126] These recent treatment guidelines and reviews emphasize the need for selecting a treatment approach based on predominant symptoms and initiating treatment in low doses with slow dose escalation.[1] Indirect comparison among the three agents approved by the FDA for FM with regard to efficacy and harms demonstrate that pregabalin, duloxetine, and milnacipran are superior to placebo for all outcomes of interest (pain, fatigue, sleep disturbance, depressed mood, and reduced health-related quality of life) except pregabalin for depressed mood, duloxetine for fatigue, and milnacipran for sleep disturbance. Adjusted indirect comparisons indicated no significant differences between these drugs for 30% pain relief and dropout rates due to adverse events.[127]

Drugs with anti-depressant activity have been a mainstay for FM treatment. Comparisons of older and newer agents have not found large differences in treatment effects, although adverse effect profiles differ.[128] Older agents, such as amitriptyline and cyclobenzaprine, may improve a wide range of symptoms, although adverse effects such as dry mouth, weight gain, constipation, and sedation may limit their tolerability.[128] Selective serotonin reuptake inhibitors typically have not been as useful as mixed reuptake inhibitors with respect to analgesic activity, although they are helpful for symptoms of depression and anxiety.[1] Older agents such as fluoxetine, paroxetine, sertraline, and venlafaxine that are not as serotonin selective thus are favored over newer, more serotonin-specific agents such as citalopram and escitalopram. These drugs are associated with nausea, sexual dysfunction, weight gain, and sleep

**TABLE 52-6** Evidence-Based Recommendations for Pharmacologic Treatments

| Class | Drug | Evidence Level | Adverse Effects |
|---|---|---|---|
| Tricyclic compounds | Amitriptyline, cyclobenzaprine | 1A | Dry mouth, weight gain, constipation, "groggy" feeling; avoid in older patients |
| Serotonin norepinephrine reuptake inhibitors | Duloxetine,† milnacipran† | 1A | Nausea, palpitations, headache, fatigue, tachycardia, hypertension |
| SSRI‡ | Fluoxetine, sertraline, paroxetine, venlafaxine | 1A | Nausea, sexual dysfunction, weight gain, sleep disturbance |
| Gabapentinoids | Gabapentin, pregabalin† | 1A | Sedation, dizziness, weight gain, peripheral edema |
| Cannabinoids | Nabilone, dronabinol | 3C | Sedation, dizziness, dry mouth |
| NSAIDs | | 5D | Gastrointestinal, renal, cardiovascular adverse effects |
| Opioids | Tramadol, other opioids | 2D, 5D | Sedation, constipation, addiction, opioid-induced hyperalgesia |

*As rated in the 2012 Canadian Fibromyalgia Guidelines.
†Approved by the U.S. Food and Drug Administration.
‡Highly selective SSRIs (e.g., citalopram and escitalopram) are not effective as analgesics.
NSAIDs, Nonsteroidal anti-inflammatory drugs; SSRI, selective serotonin reuptake inhibitor.

disturbance. The norepinephrine serotonin reuptake inhibitors duloxetine and milnacipran are approved by the FDA for treatment of FM. The addition of norepinephrine reuptake inhibition is important for achieving analgesic efficacy.[129] Time to effect for these drugs is generally 2 to 4 weeks, and thus dose adjustment and assessment of efficacy after institution of treatment should be performed within several months. Providers are cautioned to ensure that high doses or combinations of anti-depressants and concomitant medications or supplements do not result in the serotonin syndrome, which can cause agitation, tachycardia and hypertension, sweating/shivering, diarrhea, muscle rigidity, fever, seizures, and even death.

In general, agents tested and used for neuropathic pain have been more useful in FM than agents targeting peripheral mechanical and inflammatory sources of pain. Gabapentin and pregabalin are both approved by the FDA for use in postherpetic neuralgia and painful diabetic neuropathy.[130] Although only pregabalin has been approved by the FDA for use in FM, a study of gabapentin found that it also was effective.[131-133] Both gabapentin and pregabalin bind to a receptor subunit, the $\alpha 2\delta$ subunit of a calcium channel on the cell surface of neurons, to inhibit excitatory neurotransmitters.[129] There are pharmacokinetic and pharmacodynamic advantages for pregabalin that may make dosing somewhat simpler than for gabapentin, but the mechanism of actions for these drugs is the same. Both drugs may reduce pain, improve sleep, and improve health-related quality of life; however, they have substantial adverse effects, including dizziness, grogginess, weight gain, and edema of the extremities.[134] Other anticonvulsant agents have less evidence to support their use in persons with FM.

Cannabinoids are used by persons with many forms of chronic pain. A systematic review of smoked cannabis, cannabis extracts, nabilone, and dronabinol suggests modest efficacy in persons with FM and other chronic pain conditions.[135,136] NSAIDs are not effective treatments for central pain, although they may be helpful in treating inflammatory or mechanical peripheral pain generators that contribute to the overall burden of pain. Tramadol with or without acetaminophen has been studied in persons with FM, although there is increasing concern that opioids are less effective than previously thought, and their risk-benefit profile is worse than that of other classes of analgesics.[1,124] A Cochran review found no evidence to support the use of oxycodone for treatment of FM.[130] Treatment recommendations from professional societies uniformly advise against the use of strong opioids in persons with FM.[104] This recommendation is based, at least in part, on mechanistic studies demonstrating elevated cerebrospinal fluid enkephalins and evidence that mu-opioid receptors are either occupied or downregulated in the brain of persons with FM.[137] Low-dose naltrexone has been evaluated in very small trials and is thought to perhaps act on glial cells rather than on neurons.[138]

## Practical Advice

Persons with FM are likely to benefit from multimodal treatment that includes nonpharmacologic treatment, especially if one component includes exercise. In practice, it is crucial that patients be informed that there is no pharmacologic treatment that can alleviate the symptoms of FM. A general rule is that effective medications only improve pain by 30% to 50% in only 30% to 50% of patients, which includes the placebo response rate. Little information is available about combinations of approved medications, although patients with FM often use multiple medications. In general, efforts should be made to consolidate treatments and use the fewest number of medications possible. Patients should be involved in choosing nonpharmacologic strategies that will be most accepted and that are practical to employ. In addition to general nonpharmacologic approaches, it may be useful to target specific symptoms, such as sleep, with efforts to improve sleep hygiene and regulation of circadian rhythms.[105]

Many drugs and alternative therapies are used by persons who have FM and other forms of chronic musculoskeletal pain. Widespread use of nonapproved treatments reflects the generally poor effectiveness and tolerability of currently available drugs. For any treatment of FM, there is also likely to be a significant placebo effect in addition to the specific

efficacy of a therapeutic agent. It is certainly reasonable to work with patients on individual "n-of-1" trials, although it is important to assess both efficacy and harm and to discontinue use of ineffective medications or treatments with adverse effects.

## OUTCOME

The outcome of FM can be studied in terms of the change in the level of symptoms, use of services, and work disability. An early study of patients with FM who were followed up for 4.5 years found that an adequate physical activity level and increasing age predicted a positive outcome, while receiving a permanent disability pension or having experienced an excess of major negative life events predicted a negative outcome.[139] A six-center, 7-year study of 538 patients published in 1997 found that functional disability worsened slightly and health satisfaction improved slightly. Correlations between first and last assessment were often highly correlated with values for disease measures at the initial assessment predictive of final values. The authors concluded that little change in FM symptoms occurred over time.[140] A 2003 prospective study of patients with FM who were referred to a specialty clinic, 70 of 82 were reassessed after 3 years. Of these patients, 47% reported overall moderate to marked improvement, whereas the remaining 53% reported slight improvement, no change, or deterioration. The baseline predictors for a favorable outcome were younger age and less sleep disturbance.[141] Another study in the same year evaluated 27 of 48 patients who were reassessed over a 2-year time frame. In general, the patients showed no improvement in their symptoms over the observation period, regardless of the type of therapy they had received. No change occurred in either work capacity or disability-pension status. General satisfaction with quality of life improved, as did satisfaction regarding health status and the family situation.[142]

In a 2006 study intended to assess utilization of health services, 2260 patients who were seen in a primary care setting and newly diagnosed with FM were studied from 10 years before until 4 years after FM diagnosis.[47] Patients with FM had considerably higher rates of visits, prescriptions, and testing from at least 10 years prior to diagnosis compared with control subjects, and these rates accelerated to twice the numbers of visits and prescriptions at the time of diagnosis. Visit rates were highest for depression, fatigue, chest pain, headache, and sleep disturbance. After diagnosis, visits for most symptoms and health care use markers declined, but within 2 to 3 years, most visits rose to levels at or higher than those at diagnosis. The authors concluded that being diagnosed with FM may help patients cope with some symptoms but that the diagnosis has a limited impact on health care resource use in the longer term.

In a more recent longitudinal study of 1555 patients with FM during semiannual observations for up to 11 years, there was minimal improvement in symptoms overall. However, 25% reported at least moderate improvement in symptoms. These data suggested that the course of FM was one of continuous high levels of self-reported symptoms and distress.[143] Taken as a whole, although some patients improve, the data tend to suggest minimal improvement in most cases despite treatment.

A study of patients with juvenile FM (JFM) was recently reported. In this study, patients with JFM and healthy control subjects were assessed approximately 6 years after diagnosis and with an average age of 21 years. Patients with JFM had more pain, poorer physical function, and greater anxiety and depression than did healthy control subjects. They were more likely to be married and less likely to have a college education. More than 80% of patients with JFM continued to experience symptoms into adulthood, and more than half met the criteria for FM at follow-up. Those who met adult FM criteria exhibited the highest levels of physical and emotional impairment.[27]

Overall, patients with FM typically have a lifelong problem with chronic pain. Assisting patients in the self-management of their symptoms, reducing health care–seeking behaviors, and improving healthy behaviors are important goals of treatment. Perhaps the most important function of the rheumatologist is to confirm the diagnosis and determine if the patient has a comorbid rheumatic condition that should be treated. If FM is complicating another rheumatic condition, specific management of FM may improve overall health outcomes.

PART 7 DIAGNOSTIC TESTS AND PROCEDURES IN RHEUMATIC DISEASES

CHAPTER 53

# Synovial Fluid Analyses, Synovial Biopsy, and Synovial Pathology

Hani S. El-Gabalawy

**KEY POINTS**

- Analysis of synovial fluid samples by leukocyte count, cytology, polarized microscopy, Gram stain, and culture provides key diagnostic information, particularly in acute monoarthritis.
- Synovial biopsy performed by using closed needle techniques or arthroscopy may provide valuable diagnostic information, particularly in persistent monoarthritis.
- Although the histopathologic features of synovitis are generally nonspecific, some synovial diseases can be diagnosed with small synovial tissue biopsies.
- Analysis of synovial tissue by using immunohistology and other molecular techniques has been of great value in understanding the mechanisms of synovitis.
- Sequential analysis of synovial tissue samples in the context of therapeutic trials provides unique information regarding the effects of treatment on the target organ.

Analysis of synovial fluid and synovial tissue obtained from diseased joints provides important diagnostic information in specific clinical settings and is valuable in addressing a spectrum of research questions about of the pathogenesis and mechanisms of rheumatic diseases. Many peripheral joints are readily accessible to sampling of both synovial fluid effusions and synovial tissue, although the knee is the most frequently sampled joint. The techniques used to obtain and analyze synovial fluid and tissue samples are discussed in this chapter.

## SYNOVIAL FLUID ANALYSIS

### Synovial Fluid in Health

Under normal conditions, a small volume of synovial fluid is present in each joint, forming a thin interface between the surfaces of the articular cartilage, and providing for friction-free movement of these surfaces. In a large joint such as the knee, the volume of synovial fluid is estimated to be less than 5 mL. Moreover, intra-articular pressure is typically subatmospheric. Compositionally, normal synovial fluid is an ultrafiltrate of plasma to which proteins and proteoglycans are added by fibroblast-like synoviocytes in the lining layer. Most of the small-molecular-weight solutes such as oxygen, carbon dioxide, lactate, urea, creatinine, and glucose diffuse freely through the fenestrated endothelium of the synovium and are normally present at levels comparable with plasma levels. Evidence for active transport of glucose has been found. The total protein concentration of normal synovial fluid is 1.3 g/dL. The concentration of individual plasma proteins is inversely proportional to the molecular size, with small proteins such as albumin present at approximately 50% of plasma levels, and large proteins such as fibrinogen, macroglobulins, and immunoglobulins present at low levels. In contrast to this selective entry on the basis of size, clearance of synovial fluid proteins through the synovial lymphatics is unrestricted by size. Hyaluronan is the major proteoglycan synthesized by synovial cells and secreted into synovial fluid. Hyaluronan is highly polymerized and reaches molecular weights exceeding one million Daltons, which gives this fluid its characteristic viscosity. The hyaluronan also acts to retain small molecules in the synovial fluid. The lubricating capacity of the synovial fluid is attributed to a glycoprotein called *lubricin*.[1] This molecule has been fully characterized on the basis of the study of individuals with mutations of the *PRG4* gene, which encodes for its production.[2] These mutations result in an autosomal recessive loss-of-function disorder called the *camptodactyly–arthropathy–coxa vara–pericarditis syndrome*, which features a progressive, non-inflammatory arthropathy characterized by severe cartilage destruction associated with proliferation of synovial lining cells. The role of lubricin in maintaining the health of the cartilage has been further demonstrated in a murine knockout model.[3]

### Accumulation of Synovial Effusions

Synovial fluid and its contents are cleared through the synovial lymphatics by a process that is aided by joint motion. Excess fluid can accumulate in any diarthrodial joint as a result of many processes, including non-inflammatory, inflammatory, and septic disorders. In addition, overt hemarthroses can result from both traumatic and nontraumatic disorders. The most important mechanism contributing to the accumulation of joint effusions is an increase in synovial microvascular permeability. This permeability allows for an increase in the efflux of plasma proteins, particularly larger

proteins, which in turn increases osmotic pressure and contributes to the effusion. Leukocytes accumulate in the fluid after transmigration through the endothelium, stimulated by chemokines produced in the synovium. The capacity of synovial lymphatics to clear proteins, cells, and debris is rapidly exceeded, which in turn contributes to their accumulation in the synovial compartment.

## Arthrocentesis

Most peripheral joints are readily accessible for diagnostic arthrocentesis, and the procedure can be performed in almost any ambulatory care setting equipped for sterile procedures. Joints that are less accessible because of their deeper location, such as the hip, may require an imaging technique that uses fluoroscopy or ultrasound to guide the needle and ensure accurate placement. Details of techniques used for arthrocentesis are described in Chapter 54. Because the ease with which joint fluid is aspirated depends on the gauge of the needle that is used, physicians should attempt arthrocentesis with a needle of adequate gauge, particularly in the larger joints. Moreover, high-suction gradients created by large syringes should be avoided, because they may actually reduce a physician's ability to successfully aspirate synovial fluid. Difficulty in aspiration of synovial fluid may stem from a number of intra-articular factors, including viscosity, the presence of debris such as rice bodies, and loculation of fluid into inaccessible areas. Instillation of a small amount of sterile saline may help to obtain enough fluid for culture in situations in which infection is highly suspected, yet direct aspiration is difficult.

Once obtained, it is important to analyze aspirated synovial fluid samples as quickly as possible to avoid spurious results. Ideally, leukocyte count and differential should be performed on fresh specimens. If the specimen cannot be analyzed quickly, and short-term storage is needed, the specimen should be kept at 4° C. An aliquot preferably should be placed in ethylenediaminetetraacetic acid (EDTA) to prevent clotting. Delays in analysis longer than 48 hours should be avoided. A simplified algorithm for analyzing synovial fluid samples is shown in Figure 53-1.

## Gross Examination

The physician can get a first impression of the nature of the synovial fluid while fluid enters the syringe during the arthrocentesis procedure itself. For example, the viscosity of the fluid is apparent during this step. As has been mentioned, normal synovial fluid is highly viscous because of its hyaluronan content and forms a long string when a drop is expressed from the end of the needle. With increasing levels of inflammation associated with recruitment and activation of leukocytes in the synovial cavity, the hyaluronan is digested, resulting in loss of viscosity that is appreciated as a reduction in the "stringiness" of the fluid. Large pieces of debris such as rice bodies, thought to arise from detached ischemic synovial villi, may be visible while they are aspirated. These can cause sudden arrests in the flow of fluid into the syringe, requiring manipulation and redirection of needle placement.

Inspection of the aspirated synovial fluid can yield other important diagnostic information. For example, floridly purulent fluid will be completely opaque because of the very high number of leukocytes present, but synovial fluid that is transparent to the point at which printed text can be read through it is seen in non-inflammatory settings. Inflammatory synovial fluid of the type that would be aspirated from an individual with active rheumatoid arthritis (RA), appears

cloudy and translucent. The degree of translucency depends on the intensity of the inflammatory response and the concentration of leukocytes in the sample. Synovial fluid from patients with ochronosis may have a speckled appearance, and particulate debris from joint prostheses may be visible on gross inspection.

During the arthrocentesis procedure, the physician may have an important challenge in determining whether the presence of blood in the aspirated synovial fluid indicates a hemarthrosis or, alternatively, is a result of trauma from the procedure itself. In the latter case, the blood may remain unmixed with the synovial fluid, and appear as red streaks in an otherwise yellow fluid In the case of hemarthroses, the synovial fluid is generally homogeneously bloody and does not form a clot. The causes of frank hemarthrosis are varied and include trauma, pigmented villonodular synovitis, tumors, hemophilia, and other bleeding disorders or anticoagulant therapy, Charcot joint, and, occasionally, intense inflammation from a chronic arthropathy such as RA or psoriatic arthritis.

## Leukocyte Count

Analysis of leukocyte counts and cytology provide important diagnostic information regarding the cause of a synovial effusion (Table 53-1). A fresh specimen should be placed in a heparinized tube for rapid analysis and, if the fluid is particularly viscous, it may need to be diluted in normal saline before counting. Normal synovial fluid contains fewer than 180 nucleated cells/mm$^3$, most of which originate as desquamated synovial lining cells. The leukocyte count broadly classifies synovial fluids as noninflammatory (<2000 cells/mm$^3$), inflammatory (2000 to 50,000 cells/mm$^3$), and septic (>50,000 cells/mm$^3$). These definitions provide broad guidelines to help narrow the differential diagnosis rather than representing inherent biologic properties of the fluid.

The most common causes of non-inflammatory synovial fluids are mechanical derangements of the joint and osteoarthritis. Other causes include endocrinopathies such as acromegaly and hyperparathyroidism; inherited disorders such as ochronosis, hemochromatosis (which can also present with hemarthrosis), Ehlers-Danlos syndrome, Wilson's disease, and Gaucher's disease; acquired disorders such as Paget's disease, avascular necrosis, and osteochondritis dissecans; and an uncommon condition called *intermittent hydrarthrosis*, in which joints become effused in a cyclic manner. At the other extreme, leukocyte counts of 50,000 to 300,000 cells/mm$^3$ are most commonly associated with septic arthritis and should prompt the clinician to empirically treat the individual as such until this diagnosis is excluded with a high degree of certainty, which typically requires definitive culture results and, possibly, repeat aspiration. Leukocyte counts exceeding 50,000 cells/mm$^3$ are often seen in acute crystal-induced arthritis, particularly gout. Inflammatory cell counts between 3000 and 50,000 cells/mm$^3$ are seen in a wide spectrum of articular disorders, including many cases of septic arthritis. Thus, most patients with acute attacks of gout and pseudogout, active RA, reactive arthritis, and psoriatic arthritis, as well as patients with gonococcal arthritis and other nonpyogenic forms of septic arthritis, will typically present with synovial fluid cell counts in this range (see Table 53-1).

## Synovial Fluid Cytology

Characterization of the cells present in synovial fluid is an important diagnostic step that the examiner can achieve initially by performing cytology on a wet mount of the synovial fluid. To perform the wet mount analysis, the examiner places a single drop of synovial fluid on a clean glass slide, which then is covered by a coverslip and examined under low- and high-power light microscopy. In addition to leukocytes, and in the case of traumatic taps or hemarthroses, or large numbers of erythrocytes, wet mount may reveal the presence of clumps of fibrin and crystals, cartilage and synovium fragments, and lipid droplets. These can all appear as amorphous material, and care should be

**TABLE 53-1** Characteristics of Synovial Fluid

| | Appearance | Viscosity | Cells per mm$^3$ | % PMNs | Crystals | Culture |
|---|---|---|---|---|---|---|
| Normal | Transparent | High | <200 | <10% | Negative | Negative |
| Osteoarthritis | Transparent | High | 200-2000 | <10% | Occasional calcium pyrophospate and hydroxyapatite crystals | Negative |
| Rheumatoid arthritis | Translucent | Low | 2000-50,000 | Variable | Negative | Negative |
| Psoriatic arthritis | Translucent | Low | 2000-50,000 | Variable | Negative | Negative |
| Reactive arthritis | Translucent | Low | 2000-50,000 | Variable | Negative | Negative |
| Gout | Translucent to cloudy | Low | 200->50,000 | >90% | Needle-shaped, negatively birefringent monosodium urate monohydrate crystals | Negative |
| Pseudogout | Translucent to cloudy | Low | 200-50,000 | >90% | Rhomboid, positively birefringent calcium pyrophosphate crystals | Negative |
| Bacterial arthritis | Cloudy | Variable | 2000->50,000 | >90% | Negative | Positive |

PMNs, Polymorphonuclear neutrophils; PVNS, pigmented villonodular synovitis.

taken to avoid assuming their composition without further characterization.

Characterization of synovial fluid leukocytes is best achieved by staining a dried smear of the fluid. Wright stain is most commonly used for this purpose. The phenotype and morphology of the leukocytes can then be assessed under high power by using oil immersion. Septic-range synovial fluid containing more than 50,000 cells/mm$^3$ is almost always associated with a high preponderance of polymorphonuclear leukocytes, often greater than 90%. Monocytes and lymphocytes predominate in the synovial fluid of patients with viral arthritis, lupus, and other connective tissue diseases. Synovial fluid samples from patients with active RA, reactive arthritis, psoriatic arthritis, and acute attacks of crystal-induced arthritis typically demonstrate a preponderance of polymorphonuclear leukocytes, although fluids from patients with early-stage RA may have a low leukocyte count with primarily mononuclear cells. The presence of large numbers of "ragocytes," which are granulocytes that have engulfed immune complexes, is associated with active RA, and their presence may indicate an unfavorable prognosis in this disease.[4] Reiter's cells represent cytophagocytic mononuclear cells that have phagocytized apoptotic polymorphonuclear leukocytes. This may represent a pathway by which autolysis and release of damaging mediators from the latter cells are avoided.[5] The presence of Reiter's cells is not specific for reactive arthritis, nor indeed for spondyloarthropathies in general. Occasionally, eosinophils will predominate in the synovial fluid, which may be associated with parasitic infection, urticaria, or hypereosinophilic syndrome. It has been suggested that cytocentrifugation of synovial fluid is the optimum method for performing cytopathology, although the cost-effectiveness of this technique is questionable in most clinical settings.

## Wet Smear Analysis by Polarized Microscopy

A search for crystals by using polarized microscopy is particularly valuable in the diagnosis of acute monoarthritis or oligoarthritis, in which gout and pseudogout are often on the differential diagnosis. In such a clinical situation, if indeed the absence of pathogenic crystals in synovial fluid can be established, the likelihood of septic arthritis increases, prompting the initiation of intravenous antibiotics and potentially necessitating a hospital admission. Thus the rapid and accurate diagnosis of a crystal-induced process can prevent a costly and unnecessary sequence of events. It is helpful if the individual or the team that performs the arthrocentesis can also rapidly examine the specimen by polarized microscopy. For this procedure, the examiner requires a functional polarizing microscope, as well as adequate experience in the identification of crystals using this technique. This is particularly important in the case of calcium pyrophosphate crystals, which are notoriously difficult to detect.

The examiner should take care that the slide and the coverslip are free of dust, talc, and other particulate matter. Crystals present in the specimen rotate the light in such a way that they appear as bright objects in an otherwise dark field. Birefringent debris frequently are scattered throughout the slide and should not be mistaken for crystals.

The first-order red compensator is usually inserted immediately below the upper filter and serves to block out green light. Birefringent material in the specimen appears as a bright yellow or blue color in the red field generated by the first-order compensator. While birefringent crystals are rotated relative to the axis of the first-order compensator, the color changes from yellow to blue, or vice versa. Crystals that are yellow when oriented parallel to the axis of the compensator are negatively birefringent, and those that are blue are positively birefringent.

Identification of crystals in synovial fluid is greatly facilitated by detailed examination of the specimen, under both low and high power, by using the approach previously described. A combination of morphology and birefringence serves to identify the crystals. Monosodium urate (MSU) crystals, as shown in Figure 53-2, are the easiest to identify because the crystal load is typically high during an acute attack of gout. A good degree of concordance between laboratories in the identification of MSU crystals has been shown.[6-8] These crystals appear as strongly negatively birefringent needle-shaped objects, many of which are intracellular, having been phagocytized by synovial fluid leukocytes. In contrast, calcium pyrophosphate dihydrate (CPPD) crystals seen during attacks of pseudogout tend to be smaller, rhomboid-shaped objects that are weakly

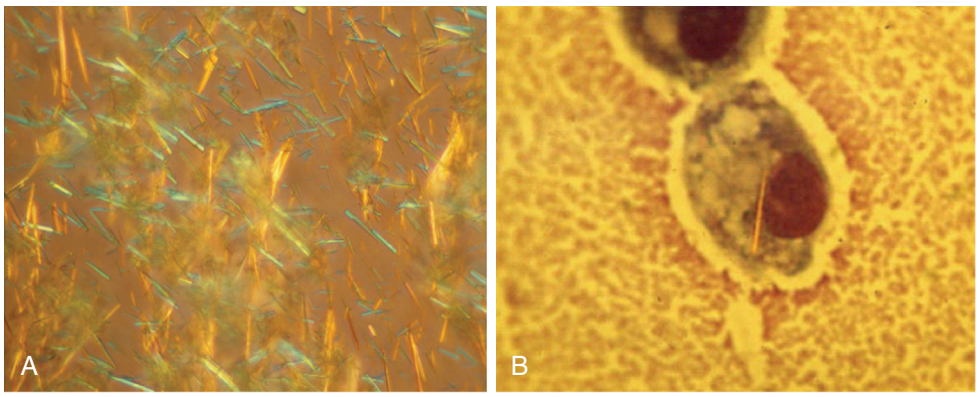

**Figure 53-2** **A,** Urate crystals in the tophus from a patient with gouty arthritis. Crystals are negatively birefringent and needle shaped. **B,** Intra-cellular urate crystal as seen on Wright stain. *(Courtesy H. Ralph Schumacher, Jr.)*

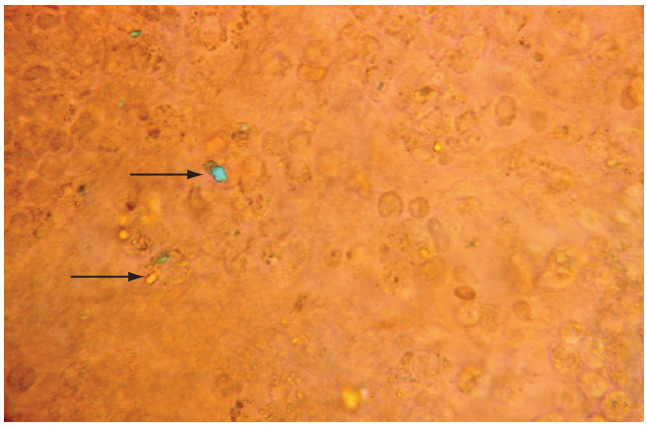

**Figure 53-3** Calcium pyrophosphate crystals in the synovial fluid from a patient with pseudogout. Crystals are positively birefringent and rhomboid shaped *(arrows). (Courtesy H. Ralph Schumacher, Jr.)*

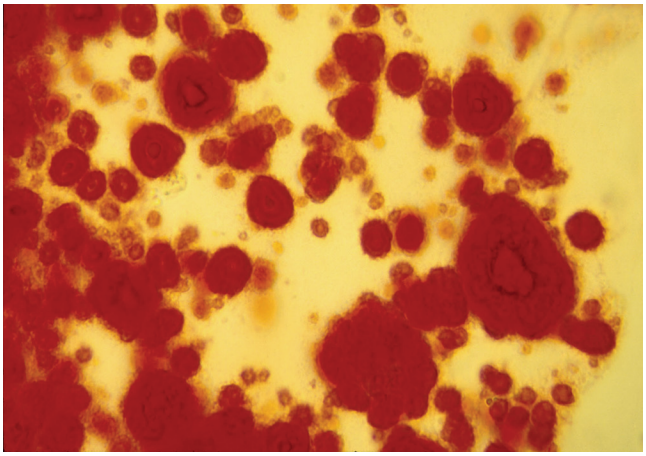

**Figure 53-4** Clumps of calcium hydroxyapatite crystals demonstrated by using alizarin red staining. Crystals are nonbirefringent. *(Courtesy H. Ralph Schumacher, Jr.)*

positively birefringent, as shown in Figure 53-3. Because the CPPD crystal load during an attack of pseudogout tends to be relatively low, and because CPPD crystals are only weakly birefringent, it is important to examine all areas of the specimen on the microscope slide, and possibly to prepare a second wet mount to exclude or confirm this diagnosis. Concordance between laboratories in the recognition of CPPD is substantially lower than in the case of MSU crystals.[6-8] A particularly challenging situation arises when intra-cellular crystals cannot be identified, yet birefringent extra-cellular objects resembling crystals are seen scattered throughout the slide. This may be caused by powder from gloves or dirt on the slides.

As with other analyses on the synovial fluid, the examiner should perform wet mount preparation and analysis as quickly as possible, although identification of crystals can still be successful after prolonged storage of specimens. The crystal load decreases substantially while the acute inflammatory attack subsides, thus making a specific diagnosis more difficult while the attack begins to subside. Urate crystals have been detected in synovial fluid between attacks of gout.

Deposits of hydroxyapatite or basic calcium phosphate are present within the joint and in periarticular locations such as around the shoulder area, and are associated with osteoarthritis. These crystals have been implicated in a particularly destructive syndrome that has been named *Milwaukee shoulder*.[9] Hydroxyapatite can be detected in synovial fluid, but because these crystals are generally nonbirefringent, it is not possible to detect them by polarized microscopy. A useful and rapid method with which to detect hydroxyapatite and other calcium-containing crystals such as octacalcium and tricalcium phosphate is to stain the fluid with alizarin red S stain and look for clumps of crystals under routine light microscopy (Figure 53-4). These crystals have also been identified by using electron microscopy, although this method is rarely available to the practicing clinician.

Synovial cholesterol crystals appear as flat, platelike structures with notched corners (Figure 53-5), and lipid crystals have the appearance of Maltese crosses. Both can be strongly birefringent, both negatively and positively.

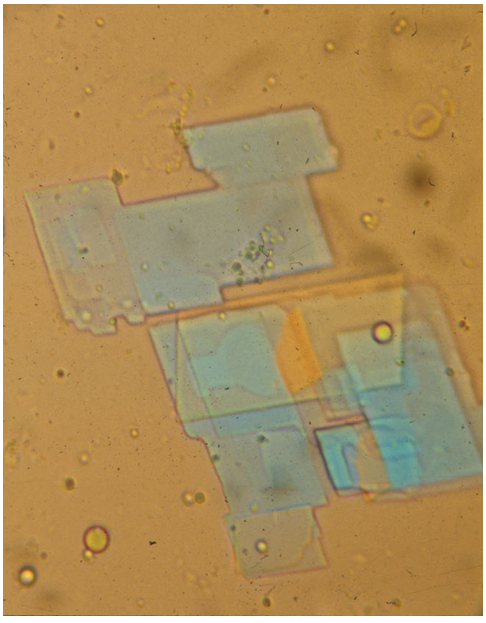

**Figure 53-5** Cholesterol crystals in a synovial fluid sample. *(Courtesy H. Ralph Schumacher, Jr.)*

Corticosteroid crystals can be highly birefringent and mimic urate or CPPD crystals. Large amounts of lipid in the synovial fluid can be visible on gross examination. The significance of these crystals in synovial fluid is unclear, but it is unlikely that they are pathogenic in most cases.

## Detection of Microorganisms by Gram Stain, Culture, and Polymerase Chain Reaction Analysis of Synovial Fluid

A wide spectrum of organisms can cause septic arthritis, although the most common pathogens are Gram-positive bacteria such as staphylococci and streptococci. Because septic arthritis causes rapid destruction of the joint, and because it can spread hematogenously to other areas and is

associated with significant mortality, it is imperative that a specific diagnosis be made as quickly as possible, and that empiric therapy with broad-spectrum antibiotics be started until this diagnosis can be confirmed or excluded.

A Gram stain performed on fresh synovial fluid will identify an organism in an estimated 50% of cases of septic arthritis,[10] with the highest sensitivity for Gram-positive organisms. Moreover, the specificity of a positive Gram stain approaches 100%. Clearly, this indicates that the positive predictive value for the Gram stain is very high, and that the negative predictive value is substantially lower. The gold standard for diagnosing septic arthritis is still bacteriologic culture, which has a sensitivity of 75% to 95% and a specificity of 90% in cases of nongonococcal septic arthritis.[11,12] The use of blood culture bottles further increases the yield of positive synovial cultures.[13] Bacteriologic cultures are the only studies that provide a guide for specific anti-microbial therapy. Because the sensitivity of bacteriologic cultures declines dramatically after antibiotic therapy is instituted, it is important that the clinician perform arthrocentesis before any antibiotics are administered. Cultures should be performed even when uric acid or other crystals are demonstrated in the synovial fluid because gout and septic arthritis can coexist.[14] In the case of gonococcal arthritis, the sensitivity of bacteriologic culture, even if performed on a sample collected by using appropriate media, is low, with an estimate of less than 10%.

Polymerase chain reaction (PCR) carries a high degree of sensitivity and specificity for the detection of microorganisms in synovial fluid and tissue, even in individuals who are culture negative.[15] Most bacteria can be detected on the basis of amplifying specific sequences in their ribosomal RNA (16S rRNA). PCR is now the procedure of choice for diagnosing gonococcal arthritis,[16,17] and is a highly sensitive and specific method of detecting tuberculous arthritis, although as discussed later, analysis of synovial tissue is better than analysis of synovial fluid for making this diagnosis.[18,19] PCR is also a method of verifying the successful elimination of the offending organism in cases of septic arthritis.[20,21]

The sensitivity and specificity of PCR in detecting synovial microorganisms should be balanced against the biologic significance of a positive test. Contaminants are easily detected by using this method, and highly stringent conditions for sample collection are required to prevent false-positive tests. Moreover, PCR studies of synovial fluid and tissue from a spectrum of chronic forms of arthritis, including RA, osteoarthritis, reactive arthritis, and undifferentiated arthritis, have indicated the presence of microorganisms in a significant number of specimens.[22,23] The biologic significance of these findings and the potential role of bacterial DNA or cell wall fragments in the pathogenesis of these arthropathies remain unclear.

## BIOCHEMICAL ANALYSIS OF SYNOVIAL FLUID

A number of widely available biochemical tests may add to the diagnostic impression of aspirated synovial fluid samples, although lack of specificity of these biochemical analyses tends to limit their value.[12,24] Testing for synovial fluid glucose, protein, and lactate dehydrogenase (LDH) has long been included in routine practice, and values obtained should be compared with serum values. Samples from septic arthritis typically exhibit very low glucose, low pH, and high lactate levels; these levels are indicative of a switch to anaerobic metabolism. Highly inflammatory synovial fluids from RA exhibit a similar profile, along with high protein and LDH levels. Levels of pressure of oxygen ($pO_2$) in the blood are often in the hypoxic range in RA synovial fluids and are correlated with increased lactate and levels of pressure of carbon dioxide ($pCO_2$) in the blood.[25,26] A prospective study conducted to evaluate these tests in a spectrum of inflammatory and non-inflammatory disorders demonstrated considerable variability in each diagnostic category, which limits their clinical utility.[24]

Serologic testing of synovial fluid to detect rheumatoid factor, anti-nuclear antibodies, and complement levels has been suggested as a method that can be used to confirm a diagnosis of RA or other connective tissue diseases. In particular, RA synovial fluids may be positive for rheumatoid factor even when serum is not,[27] and complement levels are typically low as a result of consumption by immune complexes. These findings are of insufficient sensitivity and specificity to be of value on a routine clinical basis.

### Synovial Fluid Analysis in Arthritis Research

The ease with which synovial fluid is aspirated from inflamed joints has allowed a wide spectrum of research studies to be conducted on this biologic material. In research settings, cells in synovial fluid samples are typically separated by centrifugation, and cellular and noncellular components of the fluid are analyzed separately. Detailed analysis of the phenotype and functional properties of synovial fluid leukocytes has been particularly informative in RA and reactive arthritis research, in which immunophenotyping of lymphocyte subpopulations has provided important clues to the pathogenesis of these diseases. In the case of reactive arthritis, in which triggering organisms are often identified, the proliferative and cytokine responses of synovial fluid lymphocytes to antigens derived from *Chlamydia*, *Yersinia*, and other pathogens have been elucidated.[28,29] Synovial fluid T cells from reactive arthritis patients are biased toward production of T helper (Th)2 cytokines such as interleukin (IL)-10 and IL-4, whereas synovial fluid T cells from patients with RA are Th1 biased and exhibit defects in Th2 differentiation.[30-32]

Analysis of the noncellular portion of synovial fluid has provided important information regarding a spectrum of soluble molecules, including cytokines and growth factors,[33] extra-cellular matrix proteins, autoantibodies, and therapeutic drug levels. Moreover, broad-based proteomic studies of synovial fluid with the use of fractionation techniques and mass spectrometry are beginning to provide novel approaches to understanding pathogenesis and prognosis in arthropathies such as RA.[34]

## SYNOVIAL BIOPSY

Sampling of synovial tissue is a direct approach to defining the pathologic processes that cause swollen, painful joints.. In clinical settings, it can be particularly valuable in evaluating an undiagnosed persistent monoarthritis when other

investigations, including synovial fluid analysis, have failed to provide a specific diagnosis. In research settings, analysis of synovial tissue samples has dramatically improved our understanding of the pathogenetic mechanisms underlying RA, spondyloarthropathies, and other chronic articular disorders. More recently, synovial biopsy has been explored as a method for defining the target tissue response to therapeutic agents, particularly targeted biologic therapies.

## Blind Percutaneous Synovial Biopsy

Percutaneous needle biopsy is most commonly performed according to the method originally described by Parker and Pearson,[35,36] utilizing a biopsy needle that now carries their name. Percutaneous synovial biopsy is most often performed on the knee joint, although the technique can readily be adapted for use in other joints such as the wrist, elbow, ankle, or shoulder. A modification of the original Parker-Pearson needle has facilitated synovial biopsy of small hand joints such as metacarpophalangeal and proximal interphalangeal joints.[37] The technique for Parker-Pearson synovial biopsy uses a 14 gauge needle with a lateral aperture just proximal to the inserted end of the needle. This lateral opening features a sharp cutting edge for severing trapped synovial tissue that is captured by applying suction with a 3 to 5 mL syringe. With this approach, multiple 1 to 3 mm samples are obtained by angling the trocar in several directions. This also serves to minimize the sampling error involved. Synovial samples are typically pink and are easily removed with a slight twisting motion. Because of the blind nature of the procedure, samples of fat, muscle, or fibrous tissue may be obtained and need to be separated from true synovial samples.

Percutaneous synovial biopsy is easily performed in most ambulatory care settings with the use of relatively inexpensive equipment, and recently ultrasound guidance has improved the yield. The overall morbidity of the procedure is low and is comparable with that of arthrocentesis, with perhaps a slightly higher rate of hemarthrosis. The risk of hemarthrosis can be minimized if the patient does not bear weight for a few hours after the procedure. The main disadvantage of the procedure is its blind nature. In comparison with visually guided arthroscopy, samples derived from the interface between synovium and adjacent cartilage are underrepresented when the blind procedure is used.[38,39] As discussed later, this drawback is particularly relevant to a number of research questions.

## Arthroscopically Guided Synovial Biopsy

Arthroscopy is widely used by orthopedic specialists for the diagnosis and treatment of a variety of articular disorders, particularly mechanical derangements of intra-articular structures such as cruciate ligaments and menisci. During the past two decades, the arthroscopic procedure has been adapted for diagnostic synovial biopsies in settings that do not require a fully equipped operating theater and general anesthetic. In most cases, intra-articular local anesthesia suffices for the procedure, although conscious sedation may be required in some individuals. The procedure is well tolerated and is associated with low morbidity, although the risks to the patient of hemarthrosis and infection after the procedure are slightly higher than that of percutaneous needle biopsy. The patient should be instructed to minimize weight bearing for 24 to 48 hours after the procedure.

The primary advantage of arthroscopy is its ability to visually guide the biopsy procedure. This permits macroscopic evaluation of the synovium and sampling of areas that appear to be severely affected by the pathologic process, and it allows for sampling of the interface between inflamed synovium and adjacent cartilage. This interface is an area of particular interest for understanding the pathogenesis of destructive arthropathies such as RA.[38] As with samples obtained by percutaneous synovial biopsy, individual samples are allocated for specific laboratory studies depending on the clinical or research question under investigation.

## Processing Synovial Tissue Samples

In all cases, an adequate number of individual synovial specimens need to be allocated for routine light microscopy with the use of formalin fixation and paraffin embedding. This provides the highest-quality sections for hematoxylin and eosin (H&E) histologic analysis, and it allows the most accurate delineation of pathologic processes within tissue. Although formalin-fixed sections can be used in some cases for immunohistology, formalin fixation alters the conformation of many protein antigens, making them inaccessible for specific identification by immunohistology. Many of the molecular markers used to analyze diseased synovium, including cell surface markers, cytokines, adhesion molecules, and proteases, require that tissue samples be snap frozen in a suitable mounting medium, such as optimal cutting temperature compound, and then sectioned with the use of a cryostat. The sections can be processed by using antigen-specific monoclonal or polyclonal antibodies, and color development achieved by one of several immunofluorescence or immunoperoxidase methods. Typically, a nuclear counterstain is also used to assist in orientation of the tissue—hematoxylin in the case of immunoperoxidase studies. If only formalin-fixed, paraffin-embedded tissue is available, an alternative method for detecting antigens that are sensitive to formalin fixation is antigen retrieval.

Several antigen retrieval methods are available, including enzymatic and thermal methods,[40] which have been used to successfully retrieve a spectrum of antigens from archival synovial tissue samples for immunohistologic studies, although the quality of the tissue sections often deteriorates after antigen retrieval. A number of double-staining immunohistology techniques have been developed for simultaneous evaluation of the expression of two markers in the same tissue section, although these techniques are labor intensive and often require considerable experimentation to generate good stains.[41] Formalin fixation dissolves crystals, and if this is a diagnostic consideration, the specimen should be fixed in ethanol.

The sensitivity and specificity of molecular DNA and RNA techniques provide unprecedented opportunities to explore the pathogenesis of synovial disorders. Although these studies can be carried out on very small quantities of tissue, examiners need to take great care in handling and processing tissue samples to prevent degradation of the nucleic acids, particularly with RNA when RNAase enzymes

are ubiquitous, and can rapidly degrade the small quantity of RNA present in a tissue sample. As discussed later, the search for microbial DNA and RNA has been of particular interest in attempts to understand the cause and pathogenesis of reactive arthritis, RA, and other forms of chronic synovitis of unknown cause. Techniques used to analyze human gene expression in small tissue samples have rapidly progressed. This has enabled the detection and quantitation of multiple mRNA transcripts in very small quantities of biopsy material, in many cases without the need for amplification.[42,43]

## SYNOVIAL PATHOLOGY

### Synovial Membrane in Healthy Individuals

A detailed description of the composition of normal synovium is provided in Chapter 2. Histologically, the normal synovial lining layer is one to three cells thick and is composed of closely associated macrophage-like (type A) and fibroblast-like synoviocytes (type B) that are not separated from the underlying stroma by a basement membrane, as is the case with a true epithelium. In many areas, visible gaps in this lining layer allow small molecules to easily diffuse through the extra-cellular matrix into the synovial fluid. The two types of lining layer synoviocytes are distinct and can be differentiated on the basis of ultrastructural and immunohistologic features. Macrophage-like synoviocytes are myeloid in origin, as they exhibit the morphologic characteristics of phagocytic cells and express macrophage markers such as CD68, CD14, and FcγRIIIa. Fibroblast-like synoviocytes are synthetic cells of mesenchymal origin that are the primary source of hyaluronan and other proteoglycans found in normal synovial fluid. They express CD55 (decay-accelerating factor [DAF]), high levels of vascular cell adhesion molecule (VCAM)-1, and the enzyme uridine diphosphoglucose dehydrogenase (UDPGD), which is involved in the synthesis of hyaluronan and has been detected by cytochemical methods (Figure 53-6). Fibroblast-like synoviocytes have also been shown to uniquely express cadherin-11, a specialized adhesion molecule that is involved in homotypic aggregation of these cells and that contributes to maintaining the integrity of the synovial lining layer.[44] Quantitatively, most of the cells in the normal synovial lining layer are type B cells. The underlying stroma features a rich network of capillaries with fenestrated endothelium in the immediate sublining area that serve to maintain the health and viability of adjacent cartilage. Larger arterioles and venules can be found deeper in the synovial stoma. The synovial microvasculature is surrounded by loose connective tissue, which also incorporates the synovial lymphatics that serve to drain this tissue. The synovium of completely asymptomatic individuals not uncommonly exhibits a modest infiltrate of T lymphocytes that are occasionally organized in perivascular aggregates, although B cells were not seen.[45]

### Synovial Histopathology in the Evaluation of Monoarthritis

Pathologic analysis of synovial tissue samples can be of considerable value in certain clinical settings. However, the histopathologic interpretation of synovial biopsy specimens is often nondiagnostic and lacks specificity.[46] Pathologic analysis of synovial samples from patients with undiagnosed monoarthritis may be of particular value. The presence of large numbers of neutrophils in the synovial tissue stroma is highly suggestive of septic arthritis, and in such cases Gram stain may reveal bacteria in the tissue. Because septic arthritis is usually acute in onset, synovial biopsy is rarely required, and the diagnosis can be made by analyzing synovial fluid as described previously. Gonococcal arthritis may require synovial biopsy for diagnosis (Figure 53-7). A mononuclear cell infiltrate, on the other hand, is more consistent with a chronic inflammatory process and has a wide differential diagnosis, as described previously. The presence of granulomas supports a diagnosis of tuberculous arthritis or sarcoidosis, both of which cause chronic monoarthritis. The synovial granulomas of tuberculosis (TB) may be caseating or noncaseating, and staining of the tissue for acid-fast bacilli, culture, and molecular probing can yield a definitive diagnosis in an estimated 50% of cases. Similarly, a spectrum of fungal infections can be diagnosed by using similar approaches, but special stains such as a Gomori stain may be required. The diagnosis of sarcoid arthropathy is suspected in synovial specimens with noncaseating granulomas in cases where mycobacterial or fungal infection has been excluded.

Ralph Schumacher, Jr.)*

Pigmented villonodular synovitis is an important consideration in individuals with chronic monoarthritis of a large joint such as the knee or hip. This disorder has a characteristic MRI appearance caused by hemosiderin deposits in the synovium and large cystic lesions in adjacent bone. Histopathologic analysis of the synovium can confirm this diagnosis and demonstrates a diffusely hypervascular proliferative lesion with mononuclear cells of the monocyte/macrophage lineage, foamy multinucleated cells resembling osteoclasts, and hemosiderin deposits[47] (see Figure 53-7). Synovial sarcomas are rare tumors that must be diagnosed on the basis of synovial pathology.

## Synovial Histopathology in the Evaluation of Polyarthritis

In current clinical practice, the availability of well-validated diagnostic criteria and specific serologic tests, combined with a relative lack of specificity in synovial histopathologic features, limits the clinical utility of synovial pathology in the differential diagnosis of oligoarthritis and polyarthritis. On the other hand, analysis of synovial tissue samples obtained in the context of research studies from patients with RA and various spondyloarthropathies has dramatically enhanced our understanding of the cellular and molecular mechanisms of these disorders. This is reflected in a large body of literature published during the past three decades.[38,48]

RA synovium has been the most extensively studied histopathologically, and a detailed discussion of RA synovitis can be found in Chapter 69. The two characteristic features seen in RA synovitis are hyperplasia of the lining layer and infiltration of the sublining stroma with mononuclear cells (Figure 53-8). The surface of the lining layer is often covered with fibrin deposits generated from activation of the fibrinolytic system in inflammatory synovial fluid. Occasionally, the synovial lining layer is completely denuded and is replaced by a dense fibrin cap. In highly inflamed tissues, fibrin deposits extend deeply into the sublining stroma, which may be edematous because of the marked increase in vascular permeability. The earliest synovial changes in RA appear to feature microvascular abnormalities,[49] and mononuclear cell infiltrates have been detected in asymptomatic joints of patients with RA.[50,51] These features are nonspecific and are seen in the synovium of acutely inflamed joints from a spectrum of disorders, including reactive arthritis and psoriatic arthritis.

In RA, the mononuclear cell infiltrate in the sublining stroma can be diffuse but more commonly is arranged in perivascular aggregates that resemble lymphoid follicles (see Figure 53-8). Although the presence of lymphoid aggregates in the synovial membrane is typical of RA, this histopathologic feature is by no means unique to RA synovitis.[52-55] Lymphoid follicles are typically located near vessels with tall endothelium, which are termed *high endothelial venules;* these vessels specialize in the recruitment of lymphocytes (Figure 53-9). Multinucleated giant cells are occasionally seen in RA synovium (Figure 53-10), and some tissues demonstrate granuloma formation. Finally, synovial tissue obtained at the time of joint arthroplasty often exhibits extensive fibrosis and may be indistinguishable from arthroplasty samples obtained from patients with osteoarthritis.

The synovial histopathology of psoriatic arthritis, ankylosing spondylitis, and reactive arthritis has been compared with that of RA.[56,57] In all cases, a similar spectrum of inflammatory cell populations has been identified, but

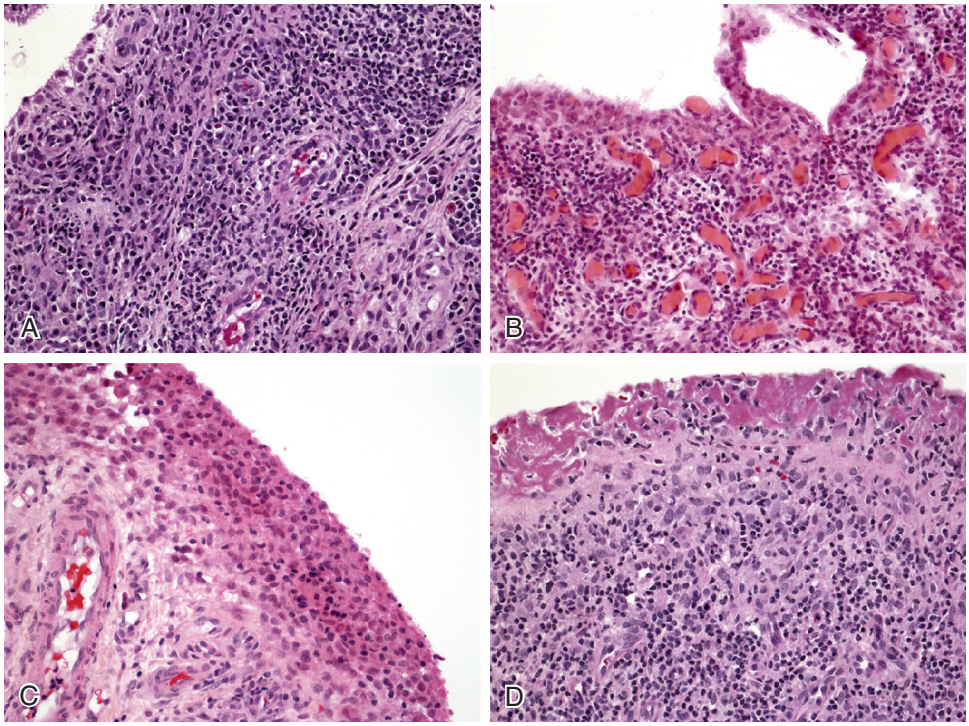

**Figure 53-8** Histopathology of rheumatoid arthritis synovitis. **A,** Lymphoid aggregate. **B,** Diffuse lymphocytic infiltrate. **C,** Hyperplasia of the lining layer. **D,** Fibrin cap replacing a denuded lining layer.

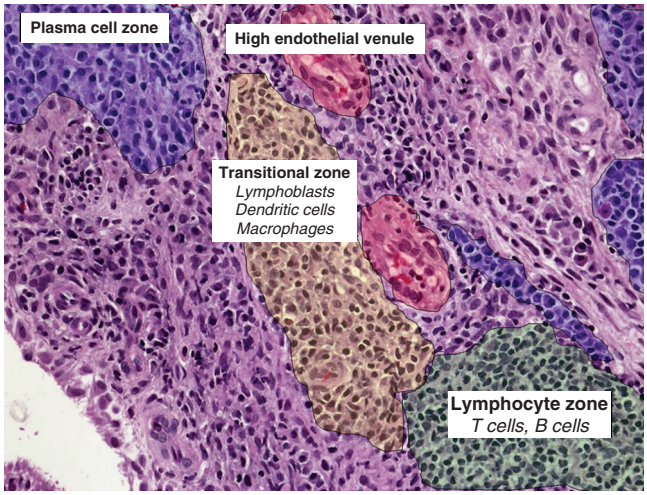

**Figure 53-9** Microarchitecture of rheumatoid arthritis synovial lymphoid aggregates.

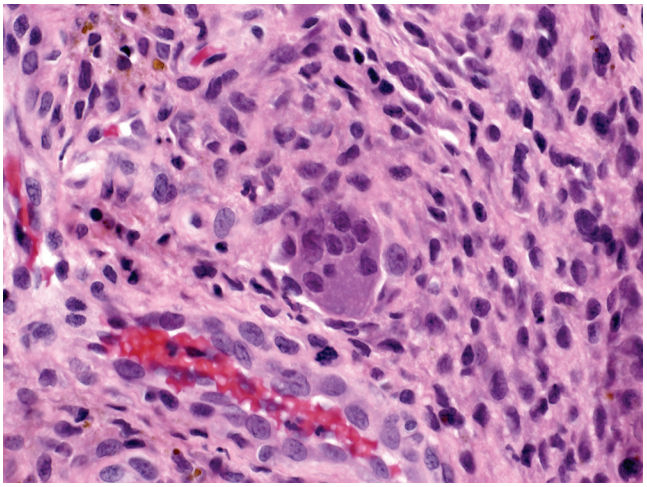

**Figure 53-10** Multinucleated giant cell in a patient with rheumatoid arthritis.

several subtle and potentially important differences have been observed. Overall, synovial histologic and immunohistologic features of psoriatic arthritis, both oligo- and polyarticular, resemble those of other spondyloarthropathies to a greater extent than RA (see Synovial Immunohistology section below).[57] Comparative studies have suggested that synovial lesions in psoriatic arthritis are more vascular than those of RA, with more tortuosity of the synovial microvasculature.[58,59] This is evident both macroscopically and microscopically. Moreover, lymphoid aggregates of various sizes were identified in 25 of 27 synovial tissue samples from patients with psoriatic arthritis, and 13 of 27 had large organized aggregates with all of the features of ectopic lymphoid neogenesis that have been associated with RA synovitis.[52] Studies of synovium from the peripheral joints of ankylosing spondylitis patients have revealed intense infiltrates of lymphocytes, plasma cells, and lymphocytic aggregates.[60,61] Comparisons made between the synovial lesions seen in patients with reactive arthritis and those seen in patients with early-stage RA of similar disease duration

suggest that reactive arthritis synovia are less infiltrated with B lymphocytes, plasma cells, and macrophages.[62,63] It should also be noted that synovium from patients with osteoarthritis often features the presence of lymphocyte aggregates, although these tend to be small and less well developed than those seen in RA.[54]

The synovium of lupus patients showed synovial hyperplasia, inflammatory infiltrates, vascular proliferation, edema and congestion, fibrinoid necrosis and intimal fibrous hyperplasia of blood vessels, and superficial fibrin deposits, although these changes were quantitatively modest compared with those of RA.[64] In early scleroderma, the lining layer was seen to be thin with deposits of fibrin and stromal lymphocytes and plasma cells,[65] and similar changes were seen in patients with dermatomyositis and polymyositis[66] (see Figure 53-7). A recent study comparing the immunopathologic features of early untreated Behçet's disease with those of psoriatic arthritis noted that although a similar degree of inflammation was seen in the two disorders, synovitis in Behçet's disease demonstrated higher numbers of neutrophils and T cells than were seen in psoriatic synovitis.[67]

In patients with chronic crystal arthropathies, large deposits of birefringent material can be detected in the synovium.[68] Amyloid arthropathy can be diagnosed by demonstrating amyloid deposits in the synovium with Congo red staining (see Figure 53-7). The synovium in ochronosis contains brownish shards of cartilage.[69] Multicentric reticulohistiocytosis can be diagnosed pathologically by the presence of large foamy cells and multinucleated cells in the synovium. In arthritis of hemochromatosis, the synovium exhibits brown hemosiderin deposits in the lining cells, and CPPD crystals can also be observed.[70]

## SYNOVIAL IMMUNOHISTOLOGY

### Sampling Error and Quantitative Analysis

Immunohistology utilizes specific monoclonal or polyclonal antibodies with well-defined molecular targets and is an effective tool for analyzing the cellular and molecular features of the synovium. While the field has progressed during the past two decades, it has become clear that algorithms for generating reproducible quantitative data from immunohistologically stained sections are required. Moreover, approaches are needed for minimizing the sampling bias that is inherent in biopsy-based studies.[71] Studies have suggested that if six or more individual specimens from different parts of the joint are examined, variance is reduced to less than 10% for T cell and activation markers.[72] Furthermore, synovial inflammatory features are similar in areas adjacent to and distant from the pannus cartilage junction, with the possible exception of macrophage numbers, which tend to be higher in adjacent areas.[73,74]

Various methods have been proposed by which quantitative data for immunohistologically stained synovial tissue sections can be generated.[75,76] The easiest and least costly method is to generate semiquantitative scores of staining intensity (e.g., on a 0 to 3 scale) from multiple areas of the tissue, and on the basis of these to obtain an average score for the entire tissue. The reliability and reproducibility of this method are increased if two observers score the tissue sections independently and a final average of the scores is generated. Computer-assisted image analysis involves capturing images from multiple areas of the tissue samples to which color-specific quantitative software algorithms are then applied. This method generates the greatest quantity of reproducible data but requires expensive equipment and certain levels of operator skill. Furthermore, differences in the background staining intensity of individual sections can make this type of analysis technically difficult.

### Synovial Lining Cell Layer

Compared with normal synovium, the lining layer in RA and other forms of chronic inflammatory arthritis is often hyperplastic, resulting from an increase in both type A and type B cells, as indicated by an increase in CD68 and CD55 staining, respectively (Figure 53-11). It is assumed that macrophage-like synoviocytes are recruited from the blood and then migrate through the synovial stroma and ultimately are retained in the lining layer in close association with fibroblast-like synoviocytes. It is currently proposed that the increase in fibroblast-like synoviocytes may be related more to defects in apoptosis than to recruitment or local proliferation. Expression of several families of adhesion molecules by both types of lining cells results in their close association and modulates their activation status. These include β1 and β2 integrins and their respective immunoglobulin supergene family ligands, particularly intercellular adhesion molecule (ICAM)-1 and VCAM-1.[77-79] Cadherin-11 expressed by fibroblast-like cells likely plays a key role in the adhesive interactions that sustain the lining layer hyperplasia.[44] This adhesion molecule is widely expressed in the lining layer of normal cells, as is shown in Figure 53-12. The relationship between fibroblast-like synoviocytes in the lining layer and other populations of mesenchymal cells in the sublining stroma remains uncertain. Immunohistology indicates that expression of CD55, VCAM-1, and cadherin-11 is primarily seen in the lining cell layer with minimal evidence of expression in sublining fibroblast populations. Similarly, our understanding of the relationship between lining layer macrophage-like cells and sublining macrophages is incomplete, and both express widely used macrophage markers such as CD68 and CD14. Seminal work from Edwards and associates has suggested that macrophage-like lining cells preferentially express FcγRIIIa receptors, which may serve to localize immune complexes to the synovium.[80]

Functionally, the lining cell layer in chronic inflammatory arthropathies such as RA and psoriatic arthritis typically has the appearance of being activated. Human leukocyte antigen (HLA)-DR is highly expressed, particularly by macrophage-like cells, which may suggest a role for these cells in antigen presentation.[81] Several studies have indicated that cells in the lining layer are the principal source of cartilage-degrading proteases, particularly matrix metalloproteinase (MMP)-1 and MMP-3[82,83] (Figure 53-13). The lining layer is generally less hyperplastic in spondyloarthropathies such as psoriatic arthritis and reactive arthritis compared with RA.[57,61,84] Less is known about the functional state of the lining cells in these disorders, although it is likely that differences compared with RA are quantitative rather than qualitative.

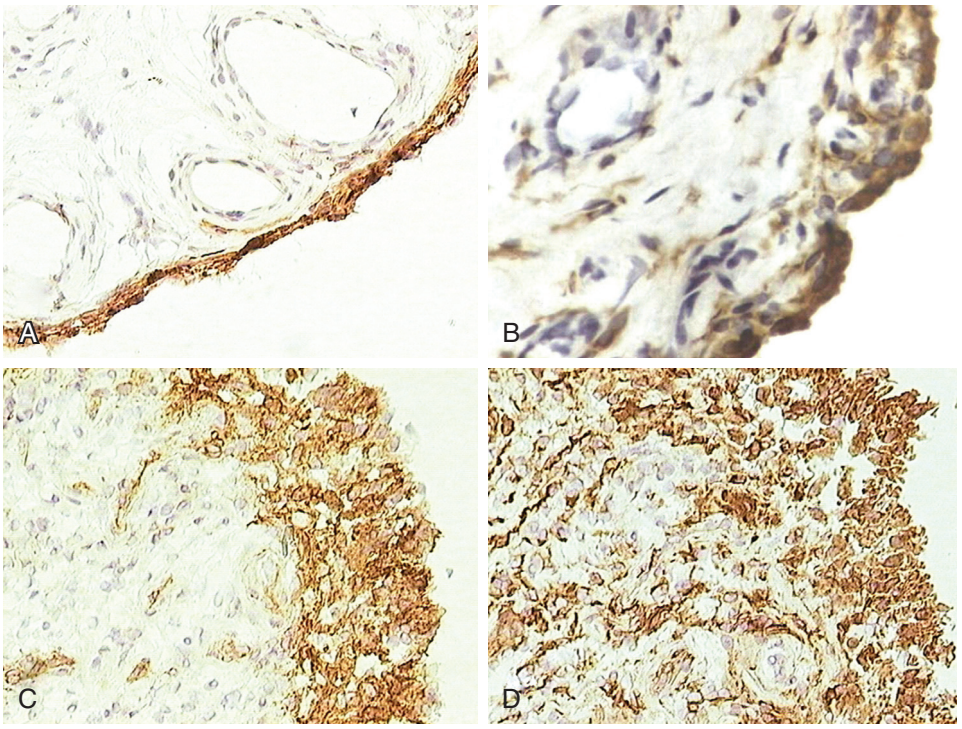

**Figure 53-11** **A-D,** Immunoperoxidase staining *(brown color)* of normal synovium and rheumatoid arthritis (RA) synovium for CD55 (fibroblast-like synoviocytes) and CD68 (macrophage-like synoviocytes). Both subsets of lining cells are increased in the hyperplastic lining layer of RA synovium.

## Synovial Lymphocytes and Plasma Cells

A predominance of $CD3^+$ T cells, is found in the synovial tissues of patients with RA and spondyloarthropathies, and the CD4/CD8 ratio is 4:1 or greater in the lymphocytic aggregates but is lower in more diffuse infiltrates. Moreover, the CD4 cells in the aggregates also express CD27,[85] which facilitates B cell help. Considerable attention has been paid to whether the infiltrating T cells in RA and other arthropathies are primarily Th1 (interferon [IFN]-γ producing) or Th2 (IL-4 producing) biased, but the data in this area have been inconsistent. Until recently, it was suggested that T cells in synovium from patients with RA are more Th1 biased compared with those in synovium from patients with spondyloarthropathies, with a higher Th1/Th2 cytokine ratio.[86] Identification of a third subset of Th cells that express IL-17 and play a central role in chronic inflammatory disorders has necessitated a revision in the role that T cells play in synovitis.[87,88] The presence of IL-17, IL-1β, and tumor necrosis factor (TNF) in RA synovium was found to be predictive of progressive damage.[89] Furthermore, a subset of CD4 T cells expressing CD25 and the gene *FoxP3*, so-called *regulatory T cells* (Tregs), are now known to play a regulatory role in antigen-specific T cell expansion. Although Tregs are readily detected in the joints of patients with RA and other inflammatory arthropathies, their suppressor function appears to be defective in this microenvironment.[90-93] It has been suggested that CD8 T cells are needed to maintain the structure of ectopic lymphoid-like structures in RA synovium, even though the numbers of these T cells typically are substantially lower than the numbers of $CD4^+$ cells.[94]

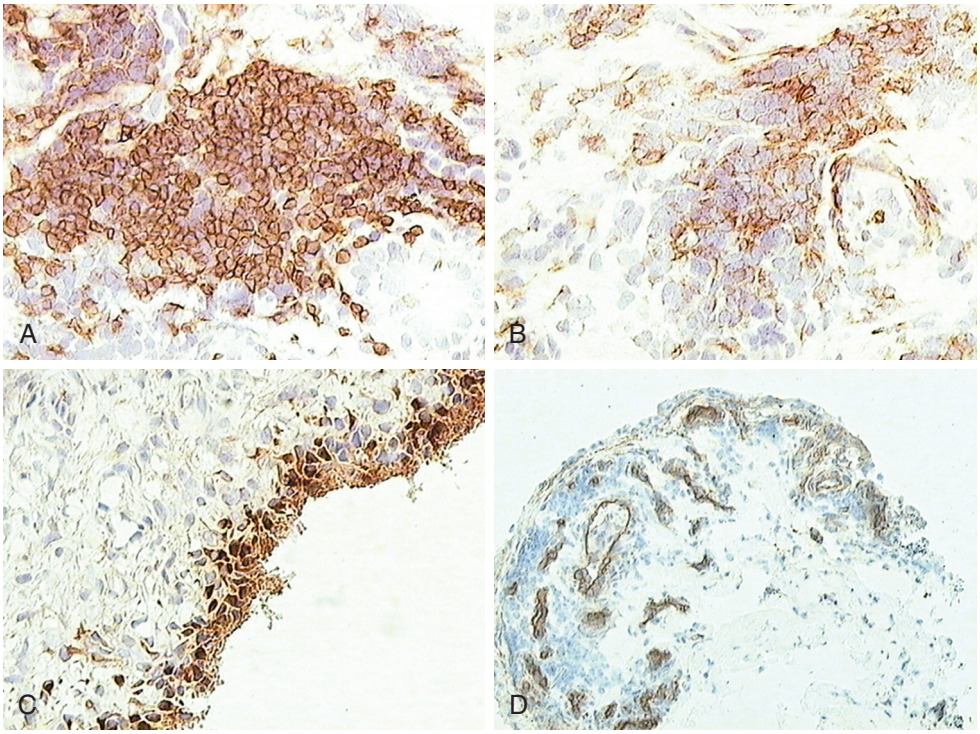

**Figure 53-13** Immunoperoxidase staining *(brown color)* of rheumatoid arthritis synovium. **A,** T lymphocytes. **B,** B lymphocytes. **C,** Matrix metalloproteinase-1. **D,** $\alpha_v\beta_3$ integrin (angiogenic vessels).

B cells are identified by expression of CD19 and CD20 and are particularly abundant in tissues that exhibit large lymphoid aggregates with germinal centers. B cells typically are found in close association with $CD4^+$ T cells in these aggregates (see Figure 53-9). Experiments in severe combined immunodeficiency (SCID) mice suggest that B cells may be critical for maintaining the microarchitecture of synovial lymphoid follicles and for T cell activation.[95] Memory B cells are efficient antigen-presenting cells, and rheumatoid factor–producing B cells are well suited for capturing a wide spectrum of antigens in immune complexes.

The areas surrounding the lymphoid aggregates are often densely infiltrated with sheets of $CD38^+$ plasma cells. Analysis of V gene variants and rearrangements in B cells and plasma cells in both RA and reactive arthritis synovium indicates that plasma cells from a particular aggregate are clonally related, suggesting that their terminal differentiation occurred in the synovial microenvironment.[96] Synovial plasma cells actively synthesize immunoglobulin, some of which result in the production of autoantibodies such as anticitrulline antibodies, which recognize local citrullinated antigens.[97-99] As stated previously, plasma cell infiltrates are also seen in psoriatic arthritis, ankylosing spondylitis, and reactive arthritis synovium, although a systematic analysis of synovial samples from patients with early arthritis has suggested that their presence is most suggestive of RA.[62] One study found that intra-cellular citrullinated proteins were detected in RA but not in spondylarthropathy synovium.[57] In contrast, another study found that the presence of citrullinated proteins was not specific for RA synovitis.[100]

The areas immediately adjacent to the dense lymphoid aggregates, which comprise primarily $CD4^+$ T cells and B cells, have been called *transitional zones*[101,102] (see Figure 53-9). These areas feature a lower CD4/CD8 ratio and appear to be particularly active immunologically. Transitional areas are rich in macrophages and interdigitating dendritic cells, both of which are highly efficient antigen-presenting cells. Lymphoblasts, in particular $CD8^+$ T cells, are seen to be present in close proximity to antigen-presenting cells.

Natural killer cells can be identified by cell surface markers, expression of granzymes, and functional assays. Several studies have suggested an expansion of subsets of natural killer cells in RA synovial tissue and synovial fluids.[103-105] Mast cells are abundant in RA synovium and co-localize with inflammatory mediators and proteases in the synovial microenvironment.[106,107]

## Synovial Sublining Macrophages and Dendritic Cells

Macrophages are present in the sublining areas of healthy and chronically inflamed synovium and are particularly abundant in the sublining stroma of RA synovium. Indeed, when markers such as CD68 and CD14 are used to study highly inflamed tissues, no clear distinction can be made between the sublining macrophage population and the macrophage-like synoviocytes present in the hyperplastic lining layer, although expression of complement receptor for C3b and iC3b was shown to be unique for lining macrophages.[108] Studies that used various macrophage markers suggest that recently migrated macrophages in perivascular areas express CD163 brightly, in addition to expressing CD68 and CD14, whereas macrophages in large lymphocytic aggregates and in the lining layer are less likely to

express CD163. $CD163^+$ macrophages, which have recently been called M2 macrophages, were found to be more abundant in spondylarthropathy than in RA synovium.[57] The functional correlates of these phenotypic differences remain unclear.[109-111] M1 macrophages, which produce TNF and IL-1β, are more abundant in RA and are under-represented in psoriatic arthritis and other spondyloarthropathies in which M2 macrophages are more abundant.[111] Furthermore, the number of macrophages in RA synovium, primarily of the M1 subset, correlates well with the destructive potential of the synovitis, as evidenced by erosive radiographic damage.[112-114] This may reflect the highly activated status of these cells, which serve as the principal source of synovial TNF and IL-1β. A body of evidence has suggested that populations of synovial macrophages serve as osteoclast precursors that mature in the synovial microenvironment and then directly mediate erosive damage to adjacent bone.[115,116]

Mature dendritic cells are the most efficient and potent of the antigen-presenting cells, and are found abundantly in inflamed synovium in close contact with T lymphocytes.[117,118] Two major subsets of dendritic cells have been described: myeloid dendritic cells (mDCs) and plasmacytoid dendritic cells (pDCs). They can be identified by immunohistology as stellate cells with dendrites that express high levels of HLA-DR and co-stimulatory molecules such as CD80, CD83, and CD86. mDCs express CD11c and CD1c, and pDCs express CD304.[119] One study suggested that compared with psoriatic synovitis, RA synovium is particularly enriched in pDCs.[119] Detailed studies that have examined the expression of chemokines involved in dendritic cell migration and recruitment suggest that a substantial proportion of dendritic cells in the synovium arrive in an immature state and subsequently undergo maturation within the synovial microenvironment in a T cell–rich area.[117,118] Follicular dendritic cells in the germinal centers of large lymphocytic aggregates express the markers CD16, FDC, and VCAM-1.

## Synovial Microvasculature, Endothelium, and Stromal Mesenchymal Cells

The stromal elements in RA are often expanded in parallel with the inflammatory cell infiltration. The microvasculature appears to be markedly increased, particularly in the deep sublining areas, and this expansion is presumed to relate to local stimulation of angiogenesis (see Figure 53-13). Morphometric studies have suggested that the number of vessels immediately adjacent to the lining layer is actually reduced compared with normal tissue.[120] This situation, combined with the metabolic demands of this tissue, may actually produce a relatively ischemic and hypoxic environment, which is reflected in the biochemical properties of RA synovial fluid.[121] Immunohistologic studies have indicated that the molecular consequences of hypoxia, particularly expression of hypoxia-inducible factor-1α (HIF-1α), a key regulator of the cellular hypoxic response, are increased in RA synovitis.[122,123] Studies that have directly measured synovial tissue $pO_2$ by using arthroscopic probes have confirmed the hypoxic nature of RA synovitis.[124-126] The synovial endothelium in RA and other inflammatory arthropathies is activated by pro-inflammatory mediators in the microenvironment to express adhesion molecules such as E-selectin, ICAM-1, and VCAM-1, which are involved in the recruitment of inflammatory cells.[127]

## Synovium-Cartilage-Bone Interface

The interface between inflamed synovium and adjacent cartilage and bone in RA and other chronic arthropathies is a site of particular interest because much of the articular damage occurs in these areas. In RA, this destructive synovial tissue is called *pannus*, which may spread to cover most of the surface of the cartilage and invade the bone in bare areas at the joint margin (Figure 53-14). Pannus has been pathologically characterized primarily from samples obtained at the time of joint arthroplasty, although arthroscopic studies at earlier stages of disease have attempted to characterize synovial samples adjacent to this area. Immunohistology suggests that synovial macrophages and fibroblasts are abundant at the pannus-cartilage interface, and that high levels of proteases are expressed by these cells. At the interface between pannus and bone, substantial numbers of multinucleated osteoclasts can be identified morphologically and by specific markers such as calcitonin receptors, cathepsin K, and staining for tartrate-resistant acid phosphatase[128] (see Figure 53-14). Moreover, expression of receptor activator of nuclear factor-κB (NF-κB) ligand (RANKL), a key cytokine in osteoclastogenesis, was prominent in these areas.[129]

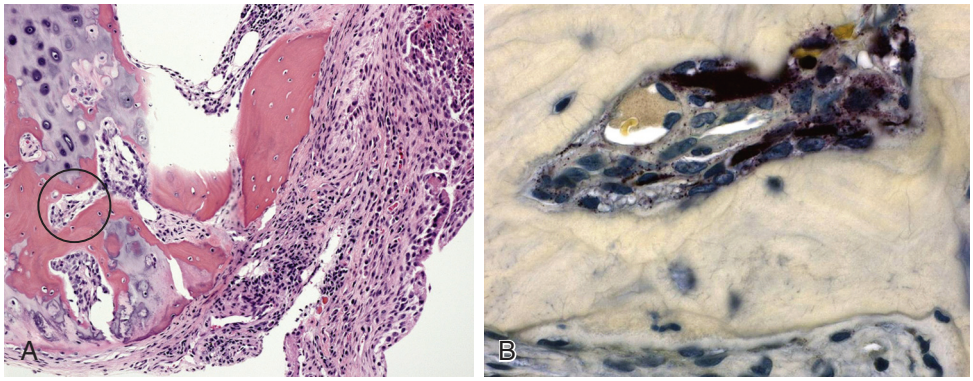

**Figure 53-14** Interface between pannus tissue and bone in a patient with rheumatoid arthritis. **A,** The synovial lesion is invading adjacent bone (see *circle*). **B,** Staining for tartrate-resistant acid phosphatase in the circled area demonstrates the presence of osteoclasts.

### Synovial Biopsy and Pathology as Research Tools for Clinical Biomarker Development

Multiple academic rheumatology centers have used arthroscopic or needle synovial biopsy and quantitative immunohistology as research tools with which to develop a better understanding of disease pathogenesis. In recent years, there has been a focus on the early clinical and preclinical stages of RA and other forms of chronic inflammatory arthritis, in the hope of devising interventions that could achieve long-term remissions and even disease prevention. In the case of RA, it is now well established that circulating autoantibodies such as RF and anti-CCP precede clinical disease onset, often by several years. [130] What is less clear is the stage where the synovium becomes engaged in the immune-inflammatory process. To address this question, synovial biopsy studies were undertaken in autoantibody-positive individuals at high risk for RA, but without clinical evidence of synovitis.[131,132] These studies failed to demonstrate significant inflammatory changes in these pre-clinical synovial samples, although there were subtle T cell infiltrates in the synovium of individuals who subsequently developed RA. These findings suggest that it is unlikely that a prolonged sub-clinical synovitis stage precedes clinical detectable joint inflammation in RA.

In individuals with established inflammatory arthritis, it has been hypothesized that analysis of the synovial lesions could provide informative biomarkers for predicting the impact of therapeutic interventions in RA and other forms of inflammatory arthritis. Such studies may be particularly valuable in predicting the effects of the expanding arsenal of targeted biologic therapies, in which the molecular target and the biologic basis of the mechanism of action are well defined.[133-146] To test this hypothesis, a recent study developed a classification paradigm for RA synovial phenotypes based on gene expression profiling and immunohistology, and found that these synovial phenotypes could be used as a source of biomarkers that correlated with response to biologic therapeutics.[142] Using a statistical classification algorithm derived from the synovial gene expression profile and concordant immunohistologic pattern of synovitis, the study identified four distinct phenotypes: lymphoid, myeloid, low inflammatory, and fibroid. These phenotypes, in particular the lymphoid versus myeloid patterns, served to predict response to infliximab treatment in a post-hoc analysis of a synovial biopsy-based clinical trial, with good responders significantly more likely to express the myeloid, M1 macrophage-dominated phenotype.[137,138] Representative soluble biomarkers were identified from the gene sets expressed by the myeloid versus lymphoid phenotype (the latter dominated by T and B lymphocyte-associated genes). These biomarkers were sICAM-1 for the myeloid phenotype and CXCL13 for the lymphoid phenotype. The serum levels of these biomarkers were found to be correlated with the clinical response to either adalimumab, a TNF inhibitor, or tocilizumab, an IL-6 receptor inhibitor, in a randomized clinical trial.[143] These results, derived from group level analyses, are encouraging, but it is too early to know how effective this approach will be in predicting response to therapeutic strategies on an individual level. They do demonstrate that synovial tissue analysis is a potentially important source of clinically relevant biomarkers.

This appealing proposition is currently hindered by several important considerations. First, the arthroscopic equipment, expertise, and infrastructure needed to undertake these studies remain limited to a small number of centers. Second, considerable concern has arisen regarding the issue of sampling bias in these studies, particularly because serial biopsies are compared in the same individual. As has been discussed, various approaches are used to minimize this bias, including systematic sampling of the same areas of the joint, computerized image analysis of multiple representative tissue samples, quantification of an adequate number of microscopic fields, and utilization of quantitative PCR and proteomic techniques to assess overall levels of specific molecules.

## CONCLUSION

Analysis of synovial fluid and tissue samples provides valuable diagnostic information in specific clinical settings. In cases in which septic or crystal-induced arthritis is suspected, as in acute monoarthritis, synovial fluid analysis is critical for the diagnosis. In cases of undiagnosed chronic monoarthritis, synovial biopsy may provide definitive evidence of conditions such as TB, sarcoidosis, and pigmented villonodular synovitis.

Systematic analysis of synovial tissue in RA and other forms of inflammatory arthritis, particularly with the use of immunohistology, has provided a wealth of information concerning the cellular and molecular mechanisms that sustain synovial lesions. Research protocols are currently exploring the utility of synovial biopsy in predicting response to anti-rheumatic therapies.

CHAPTER 54

# Arthrocentesis and Injection of Joints and Soft Tissue

Ahmed S. Zayat • Maya Buch • Richard J. Wakefield

**KEY POINTS**

- Arthrocentesis (i.e., joint aspiration) is a key diagnostic procedure in rheumatology, especially when patients have an acutely hot and swollen joint on presentation.
- Injections of joint and soft tissues can be an effective primary or adjuvant therapeutic approach in some rheumatic and musculoskeletal disorders.
- Knowledge of joint anatomy and supervised training are essential for safe practice.
- The right indication, proper technique, and good postinjection care improve procedure outcome.
- Procedure technique can vary between clinicians. However, certain anatomic facts and best practice techniques should always be considered.
- Ultrasound guidance can be used if available and if a blinded procedure has failed to obtain a synovial fluid sample or improve symptoms. For some joints, however, an ultrasound-guided procedure may be the preferred first-line approach.

The ability to target a needle to the exact site of pathology is an essential aspect of patient management in musculoskeletal care. Needles do not only allow the accurate placement of local therapies (e.g., corticosteroids), but also allow fluid to be withdrawn for both diagnostic (e.g., excluding crystals and infection) and therapeutic reasons). Localized injections may be placed in joints or periarticular soft tissues. Different injectants have been used as therapies during the last century, but corticosteroid and local anesthetics are still the most common agents used by most clinicians around the world. Some clinicians continue to use hyaluronic acid and yttrium. To perform such interventional procedures, a good knowledge of anatomy and supervised experience is required to reduce potential complications and improve outcome. Although conventionally, needle interventions are done blinded (with the exception of some fluoroscopic-guided procedures), ultrasound-guided aspirations and injections are increasingly used by rheumatologists because this technique is increasingly available in clinics. Ultrasound guidance has the advantage of confirming the need for the procedure (by providing evidence of the presence of inflammation) and allowing real-time visualization of the needle site and therefore more accurate placement of drugs. However, this technique requires an appropriately skilled operator and more time than other procedures. It may therefore be reasonable to restrict the use of ultrasound for joints that do not respond to a blinded injection and those that are conventionally difficult to do with a blinded injection (e.g., the hip joint).

## INDICATIONS AND CONTRAINDICATION OF ARTHROCENTESIS AND SOFT TISSUE INJECTIONS

A wide range of indications exist for arthrocentesis and injections of joints and soft tissues. The first, most important, indication for arthrocentesis is diagnostic joint aspiration. This is a critical procedure to rule out septic arthritis in patients who are first seen with a hot swollen joint. Joint aspiration can provide fluid for both macroscopic inspection (e.g., pus or hemarthrosis) and laboratory analysis (Table 54-1). Synovial fluid laboratory analysis can confirm the presence of crystals (e.g., sodium monourate crystals in gout) or rule out infection. Joint aspiration and drainage have also a symptomatic relief effect by reducing pain from severe joint distension. Joints injections may be used to deliver pharmacologic agents locally to treat various musculoskeletal conditions. Joints injections can help to treat treat persistent synovitis/recurrent effusion in monoarthritis, oligoarthritis or polyarthritis when systematic treatments fail or are not indicated. In inflammatory conditions such as rheumatoid arthritis (RA) or crystal arthropathies, the effect of steroid joint injections tends to be better and longer lasting than in osteoarthritis (OA), in which effects may be short lived or nonexistent.[1] It helps reduce pain and swelling and improve range of movement. Steroid injections are also indicated for a range of soft tissue conditions, such as trigger fingers, tenosynovitis, enthesopathies (e.g., epicondylitis), bursitis, adhesive capsulitis, rheumatoid nodules, and entrapment neuritis (e.g., carpal tunnel syndrome). When performing procedures, it is essential to check for contraindications and warn about potential complications (Table 54-2).

## DRUGS AND PREPARATIONS USED FOR INJECTION

During the years, different preparations have been investigated for potential intra-articular use, ranging from the very early trials of Lipiodol (poppy seed oil) and Jodipin (product of sesame oil)[2] to the very recent intra-articular injections of cultured stem cells.[3] However, crystalline corticosteroid preparations appear to have the best evidence in improving joints inflammation and reducing pain.[4] Local anesthetics have been used in conjunction with corticosteroids to provide immediate relief of symptoms and to help identify

**TABLE 54-1** Macroscopic and Microscopic Appearances of Synovial Fluid in Different Conditions

| Diagnosis | Appearance | Viscosity | Special Findings | Cellularity |
|---|---|---|---|---|
| Normal | Clear-yellow | High | Nil | Few cells & little debris |
| Inflammatory arthritis | Cloudy | Low | | >90% polymorphs |
| Osteoarthritis | Clear-yellow | Very high | | < 50% polymorphs |
| Gout | Cloudy | Mild low | Monosodium urate crystals (needle-like) | >90% polymorphs |
| Pseudogout | Cloudy | Mild Low | Calcium pyrophosphate crystals (rhomboid) | >90% polymorphs |
| Septic arthritis | Turbid or purulent | Low | Culture positive | >90% polymorphs |
| Hemoarthrosis | red | High | Blood | Blood |

**TABLE 54-2** Important Considerations Prior to Joint Injection

| |
|---|
| Avoid performing joint injections in the following situations (if you have clinical suspicion, do not inject with corticosteroid): |
| • Prosthetic joint (needs to be done by orthopedic surgeon in a sterile environment) |
| • Cellulitis or leg ulcers on same limb, psoriasis, or eczema at injection site |
| • Systemic infection |
| • Raised internalized normalized ratio (INR) (e.g., because of warfarin [>2.5] or bleeding disorder) |
| • Drug allergy to corticosteroid or local anesthetics |
| Some orthopedics specialists prefer for patients not to have joint injections at least 3 months before joint replacement. |
| Always explain the following potential complications: |
| • Postinjection flare (uncommon and can occur after a few hours as long as 24 to 48 hours after injection) |
| • Septic arthritis (rare, incidence increases in the elderly or immunocompromised) |
| • Bleeding (review if the patient is taking warfarin; relatively safe if INR <2.5; avoid deep joints and use of large-gauge needles if patient is on warfarin) |
| • Tendon rupture (do not inject against resistance, avoid injecting Achilles tendon) |
| • Fat and skin atrophy and depigmentation of the skin around the injection site (avoid injecting superficial structures with potent corticosteroids preparations) |
| • Misplaced intravascular injection (always aspirate before injection) |
| • Neurovascular image (always know the anatomic landmarks of these structures before injecting) |
| • Cartilage damage (may occur with multiple frequent injections) |
| • Allergic reaction to local anesthesia (check allergy history) |
| • Flushing and/or palpitations (within 24 hours of injection from systematic absorption of steroid) |
| • Possible transient increase in blood glucose level if patient has diabetes mellitus |

the accurate placement of the injection, by observing whether the area to which the anesthetic is applied shows immediate relief of symptoms. Methylprednisolone and triamcinolone are the most commonly used crystalline corticosteroids for treating joints, with similar outcomes in some studies.[5] Hydrocortisone is a weak soluble preparation of corticosteroid that is often used, preferably for soft tissue or superficial injections, to reduce risk of skin depigmentation or fat atrophy; however, it tends to be less effective, and the effects are shorter lived than with methylprednisolone and triamcinolone. In this chapter, some suggestions for type of preparation and the dose are provided. However, the specific clinical circumstances and the relative risks and benefits of long acting and short acting agents should be considered for each patient.

Some clinicians prefer not to mix corticosteroid with local anesthetics because this may lead to precipitation of the corticosteroid or have a putative chondrotoxic effect in vitro.[6,7] However, anecdotal evidence suggests that mixing lidocaine with crystalline corticosteroid is a common practice, with no increased procedure risk. Premixed preparations are currently available from manufacturers. Lidocaine hydrochloride (1% and 2%) and bupivacaine HCl (0.25% and 5%) are the most commonly used local anesthetics. Lidocaine starts acting within 30 seconds, and the effects last as long as 1 hour. It is useful for painful procedures and for testing for accurate placement of the injection. However, if a longer local anesthetic effect is required (e.g., for a suprascapular nerve block), bupivacaine starts to act after 30 minutes, and the effect can last as long as 8 hours. This longer effect can also be useful if the patient has previously reported a postinjection pain flare up. Worldwide, many rheumatologists use hyaluronic acid derivatives to treat osteoarthritic joints. Hyaluronic acid derivatives are believed to act by replacing the synovial fluid in the joint to function as a lubricant, shock absorber, and an anti-inflammatory agent. They have been reported to be useful for relatively longer pain relief in OA.[8]

## PROCEDURES DESCRIPTION

Clinicians need to perform joint aspiration and injections using considered and specific approaches for good localization of the needle and reduced risk of complications (Table 54-3). Clinicians often use varied approaches and different preparations. These descriptions therefore reflect the authors' own practice, but the general principles described in the text should still apply for the procedure to be safe and effective. Ultrasound-guided arthrocentesis is not necessarily performed according to the traditional approach, but the approach is made upon the access window found in ultrasound, and the structures are visualized. The techniques described will be divided into procedures for

**TABLE 54-3** Elements Required for Successful Injection

| |
|---|
| Choose a quiet and uninterrupted environment. |
| Always use aseptic technique. Mark before cleaning. Once the injection area is cleaned, do not touch it unless complete asterile conditions apply. |
| Always aspirate before injecting to avoid intravascular placement of a large volume of lidocaine or crystalline steroid. |
| Never force an injection against resistance to avoid risk of tendon/ligament rupture. |
| If difficulty is encountered or there is resistance to injection, withdraw slightly and change the needle direction. |
| Always document procedure in patient notes. Documentation should include confirmation of verbal/written consent, patient understanding of potential complications, confirmation of aseptic approach, and drug used. |

intra-articular and for soft tissue injections. The technique for each procedure will be described for both upper and lower limbs, beginning with the distal and moving to the proximal joints. When ultrasound is commonly used in a technique, this approach will be described accordingly. The images shown in this chapter only show the hand that is used to hold the needle. In practice, the other hand is used to hold the position of the joint steady.

## UPPER LIMB INJECTIONS

### Proximal Interphalangeal Joint Injection

These joints are often injected for symptomatic OA or joints that do not respond to systemic treatment for RA. The aim of an intra-articular injection is to place the needle tip within the joint capsule, and not specifically within the joint space (i.e., directly between the bones).

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe (an insulin syringe can be used as well), and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisolone, 5 to 10 mg (±0.2 mL 2% lidocaine).

*The procedure is as follows:*

1. Palpate and mark the proximal interphalangeal joint (PIP) joint space medial or lateral to the extensor tendon on the dorsal aspect of the finger.
2. Insert the needle obliquely to the skin from the dorsolateral or mediolateral position with the tip of the needle passing under the extensor tendon (Figure 54-1). Aspirate and then slowly inject the needle. The capsule of the joint should be felt to slowly distend. Follow the general postinjection care steps.

### Metacarpophalangeal Joint Injection

This injection can be indicated for solitary inflamed metacarpophalangeal (MCP) joints that are not responding to conventional or systemic therapy. Occasionally, they may also be used for symptomatic OA.

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe (an insulin syringe can be used as well), and a preparation of methylprednisolone, 10 mg (±0.2 mL 2% lidocaine).

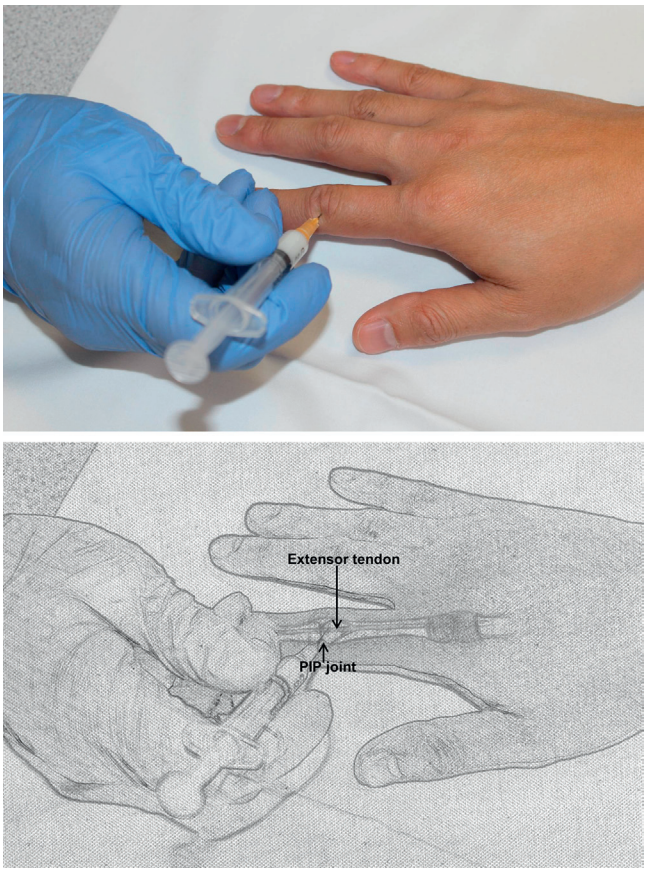

**Figure 54-1** Proximal interphalangeal joints (PIP) joint injection.

**TABLE 54-4** Considerations for Possible Crystal Arthropathies

| |
|---|
| If infection is considered, send fluid to laboratory in a plain universal container—mark as urgent, contact laboratory asking for urgent microscopy/culture and subsequently positively seek result. |
| Negative result for crystals from laboratory does not rule out crystal disease. |
| If you have access to a polarizing microscope, check for crystals yourself. Monosodium urate crystals are needle shaped, negatively birefringent while calcium pyrophosphate crystals are short, thick, and negatively birefringent. |

*The procedure is as follows:*

1. Palpate and mark the MCP joint space medial or lateral to the extensor tendon from the dorsal side. A radial approach is preferred for the second MCP joint.
2. With the joint slightly flexed, the needle is inserted below the extensor tendon inside the joint capsule, as with the PIP joint (Figure 54-2). Aspirate, and then slowly inject the syringe. Follow the general postinjection care steps.

### Wrist Joint Injection

Aspiration of the wrist can be useful in ruling out septic or crystal arthropathies. Table 54-4 has more information. In cases of symptomatic inflamed wrist joints, regardless of systematic therapy, steroid injection can be indicated. The

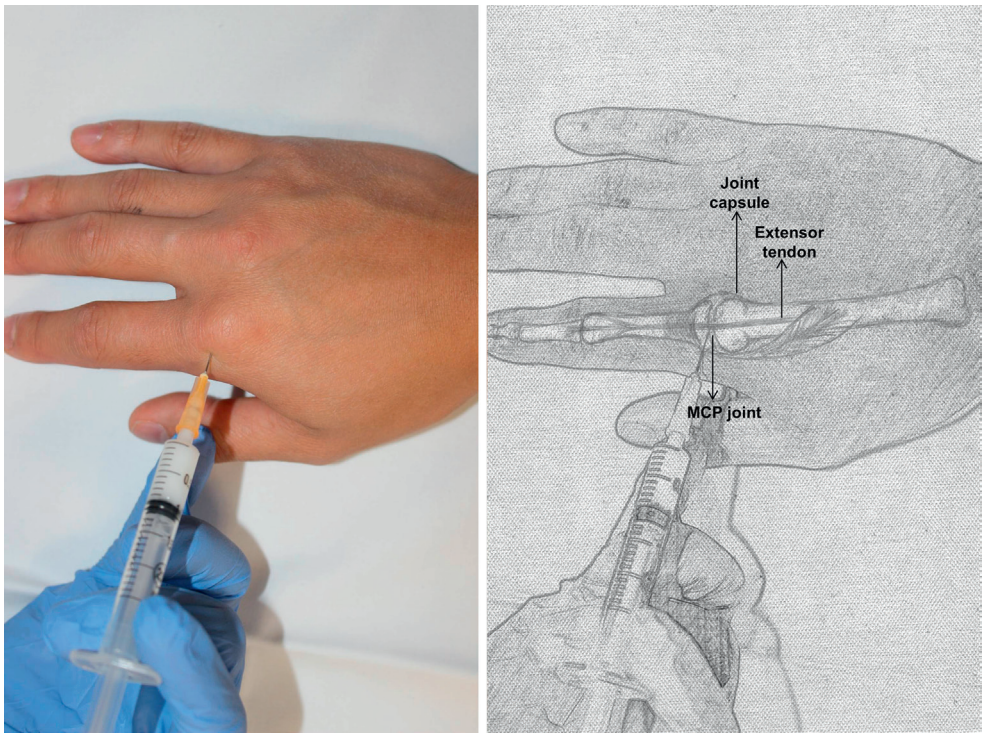

**Figure 54-2** Metacarpophalangeal (MCP) joint injection.

best entry for needle placement is the gap between the third (extensor pollicis longus) and fourth extensor tendon (extensor digitorum) compartments (Figures 54-3 and 54-4A).

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe (an insulin syringe can be used as well), and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisolone, 10 mg (±0.2 mL 2% lidocaine).

*The procedure is as follows:*

1. Feel for the joint line by flexing and extending the wrist. The gap can be easily felt near midline just ulnar and slightly distal to the Lister's tubercle.
2. Insert the needle perpendicular to skin at the joint line. Aspirate and then slowly inject the syringe. Follow the general postinjection care steps.

For ultrasound-guided injection, the gap between the fourth and fifth extensor tendon compartments can be used (Figure 54-4).

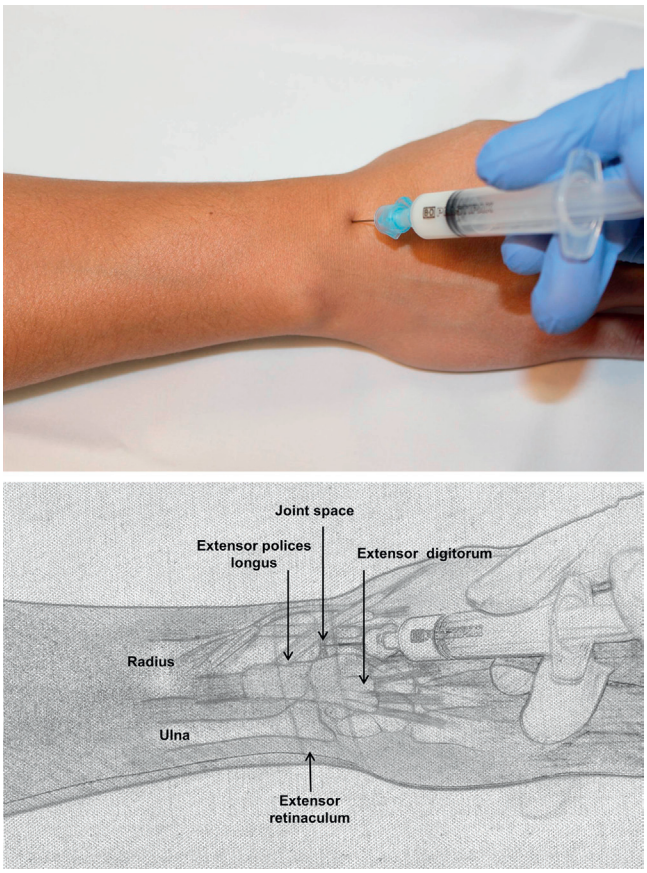

**Figure 54-3** Wrist joint injection.

## Elbow Joint Injection

This procedure is indicated for elbow monoarthritis or oligoarthritis. When you perform the procedure, you should be aware of the ulnar nerve, which lies medially (on the ulnar side) and passes in the ulnar groove between the medial epicondyle and olecranon process. Thus a radial approach is highly recommended.

Materials needed for the procedure are a 23-gauge needle, a 5 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisolone, 20 to 40 mg (±2 mL 1% lidocaine).

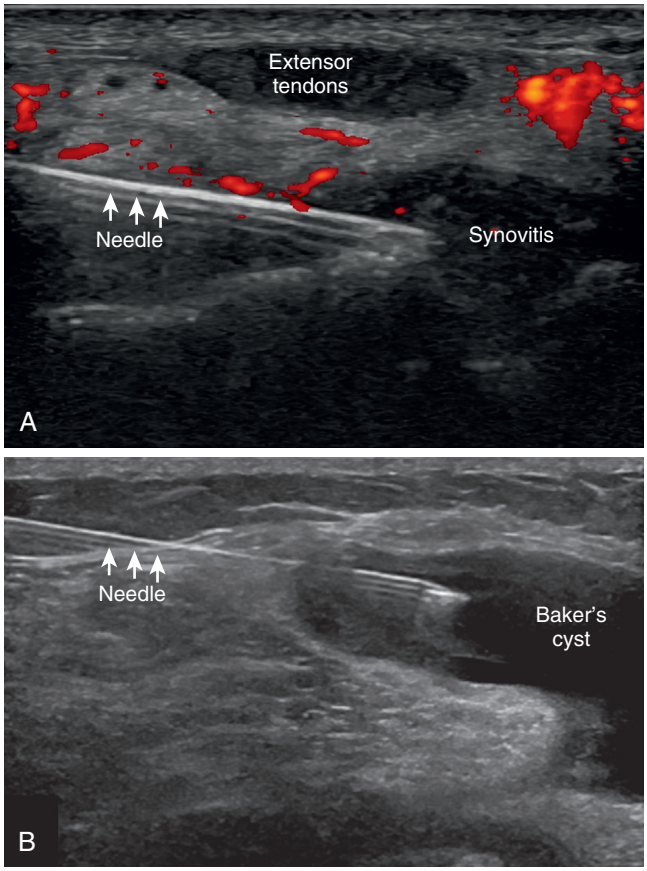

**Figure 54-4** Ultrasound image. **A,** Wrist joint. **B,** Baker's cyst injection.

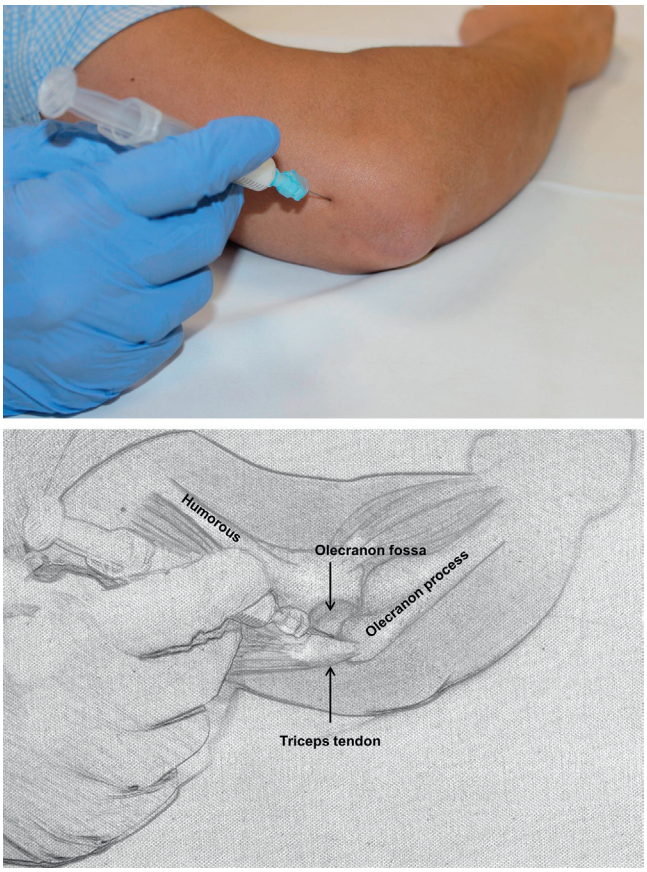

**Figure 54-5** Elbow joint injection.

*The procedure is as follows:*

1. Place the patient in the supine position with the elbow flexed 90 degrees and placed over the chest.
2. Palpate and mark the cleft between the lateral epicondyle and olecranon process. Insert the needle perpendicular to the skin radial to triceps tendon, aiming distally (Figure 54-5). Aspirate and then slowly inject the syringe. Follow the general postinjection care steps.
3. Injection medial to the olecranon process should be avoided (caution: ulnar nerve).

## Shoulder Joint (Glenohumeral) Injection

Shoulder OA, RA, and frozen shoulder are the main indications that glenohumeral injections are needed. We recommend injecting from the posterior side because this approach has no overlying neurovascular structures (Figure 54-6).

Materials needed for the procedure are a 21-gauge needle, a 5 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisolone, 20 to 80 mg (±1 mL 1% lidocaine).

*The procedure is as follows:*

1. Place the patient in the sitting position with his/her back to you.
2. Feel the joint 2 to 3 cm inferior and medial to the acromial tip. Internally and externally rotating the joint may help confirm the joint line. Advance the needle in an anterior direction. Ensure the plunger has very little or no resistance when injecting. Try to aspirate before slowly injecting the syringe. Follow the general postinjection care steps.

## Acromioclavicular Joint Injection

The acromioclavicular joint (ACJ) is a synovial joint with a very small joint space; as a consequence, only a small amount of fluid can be injected. Direct or indirect ultrasound guidance can help to ensure the correct placement of the injection, especially if there is suspected osteophytosis and loss of joint space.

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe (an insulin syringe can be used as well), and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisolone, 10 mg (±0.2 mL 2% lidocaine).

*The procedure is as follows:*

1. Palpate and mark the ACJ.
2. Insert the needle directing inferiorly and slightly posteriorly, aiming toward the center of the joint space (Figure 54-7). The joint is surrounded by tough ligaments that may produce some initial resistance to the needle. Aspirate and then slowly inject the syringe. Follow the general postinjection care steps.

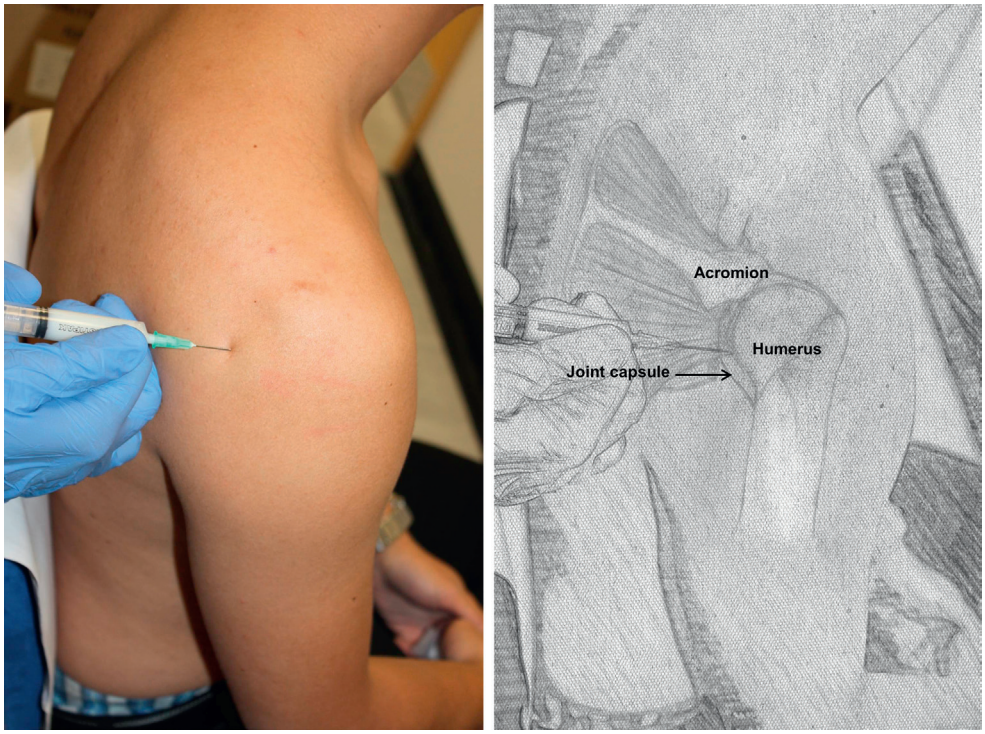

**Figure 54-6** Shoulder joint (glenohumeral) injection.

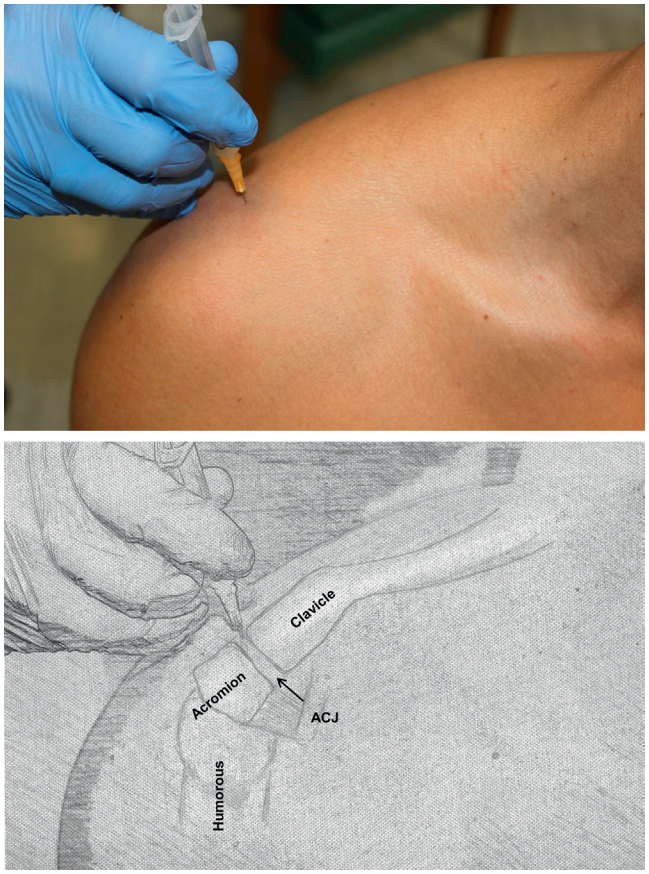

**Figure 54-7** Acromioclavicular joint injection.

# LOWER LIMBS

## Metatarsophalangeal Joint

Injection and aspiration of metatarsophalangeal (MTP) joints (including commonly the first MTP joint) can be used particularly for gout diagnosis and treatment and reduction of MTP joint OA symptoms.

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe (an insulin syringe can be used as well), and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisolone, 5 to 10 mg (±0.2 mL 2% lidocaine).

*The procedure is as follows:*

1. Palpate and mark the MTP joint space medial or lateral to the extensor tendon from the dorsal side. A medial approach is preferred for the first MTP procedure.
2. Insert the needle perpendicular to the skin, with some plantar flexion of the MTP joints. Aim to inject under the extensor tendon (Figure 54-8). Aspirate and then slowly inject the syringe. Follow the postinjection care steps.

## Midfoot Joints (Talonavicular and Navicular Cuniform)

Direct or indirect ultrasound guidance is preferred for these joints, because they are narrow and difficult to locate by palpation, especially if coexistent OA is present. In indirect placement, the place of entry can be identified and marked by using a surgical marker in both longitudinal and transverse ultrasound view. A cross-mark can be made where the two lines meet. After the probe is removed, the needle can be inserted into the center of the cross-mark.

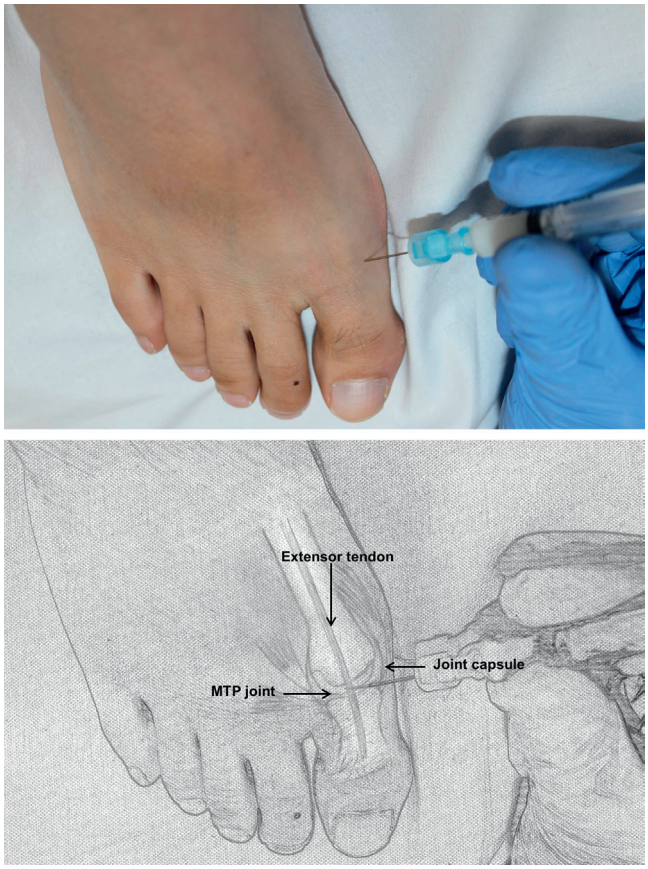

**Figure 54-8** Metatarsophalangeal (MTP) joint injection.

## Ankle (Tibiotalar) Joint

Both anterior and posterior blind approaches for ankle joint injection can be used. However, the anterior approach, which is easier and less painful, will be described in this chapter. The clinician performing the ankle injection needs to be aware of specific anatomic structures to help identify the correct location, reduce the risk of complications, and improve the outcome of the procedure. One important structure is the dorsalis pedis artery, which lies just lateral to the extensor hallucis tendon (EHL) at ankle level. The EHL can be identified when the big toe is extended. The clinician is advised to palpate the artery to avoid injecting it. The deep peroneal nerve, which innervates the leg muscles that raise the feet and toes during walking, runs medial to the EHL, crosses behind the tendon 1 to 1.5 cm proximal to the ankle, and is located lateral to EHL tendon at ankle joint space level. Because of these anatomic structures, we recommend making the injection medial to the EHL.

Materials needed for the procedure are a 23-gauge needle, a 5 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisolone, 20 to 40 mg (±2 mL 1% lidocaine).

*The procedure is as follows:*

1. Place the patient in the supine position with ankle in dorsal extension.
2. Identify the joint line by having the patient flex and extend the joint (the joint can be more proximal than expected by just looking at the surface anatomy; thus palpation is strongly recommended).
3. Insert the needle medial to the tibialis anterior tendon (the tendon just medial to the EHL). Direct the needle posteriolaterally tangent to the curve of the talus (Figure 54-9). Aspirate and then slowly inject the syringe. Follow the general postinjection care steps.

## Subtalar Joint

The subtalar joint is the articulation between the talus and calcaneus tendon. This injection can be difficult if done blind, because the joint is very narrow and covered with thick capsule and cartilage. Thus ultrasound guidance is recommended. The lateral approach is preferred because of the lesser risk of damage to neurovascular structures and the ease of identifying the sinus tarsi. The talocalcaneal ligament is inside the joint; thus it can produce resistance to the needle during the procedure.

Materials needed for the procedure are a 23-gauge needle, a 5 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisolone, 20 to 40 mg (±2 mL 1% lidocaine).

*The procedure is as follows:*

1. Place the patient in the supine position and the ankle in the inversion position.
2. Identify the joint line by eversion and inversion of the joint. The joint line is anterior and inferior to lateral malleoli.
3. Insert the needle perpendicular to the direction toward the medial malleolus for approximately 1 inch (Figure 54-10). Insert the needle through the resistance of the ligament until you feel the tissue give; this indicates that you are in the joint space. Aspirate and then slowly inject the syringe. If you feel high resistance to the plunger, it means you are still in the ligament. Push the needle further until you can easily inject the plunger. Follow the postinjection care steps.

## Knee Joint Injection

This is one of the most common procedures performed. It is usually indicated for aspirations for diagnostic or therapeutic purposes to relieve the knee synovitis present with inflammatory arthritis and crystal arthropathy or secondary to OA. When performing the knee injection, the clinician should aim to inject the suprapatellar pouch (SPP) rather than the tibiofemoral joint. The SPP is a large bursa-like structure that extends behind the upper half of the patella and quadriceps tendon and is connected to the knee joint space.

Materials needed for the procedure are a 21-gauge needle, 5 mL syringe (a long needle is needed in cases of obesity), and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisolone, 20 to 80 mg (±3 mL 1% lidocaine).

*The procedure is as follows:*

1. Place patient in a supine position with the knee in a relaxed and slightly flexed position (the knee can be supported with a rolled towel or pillow to help with relaxing in the bent position).

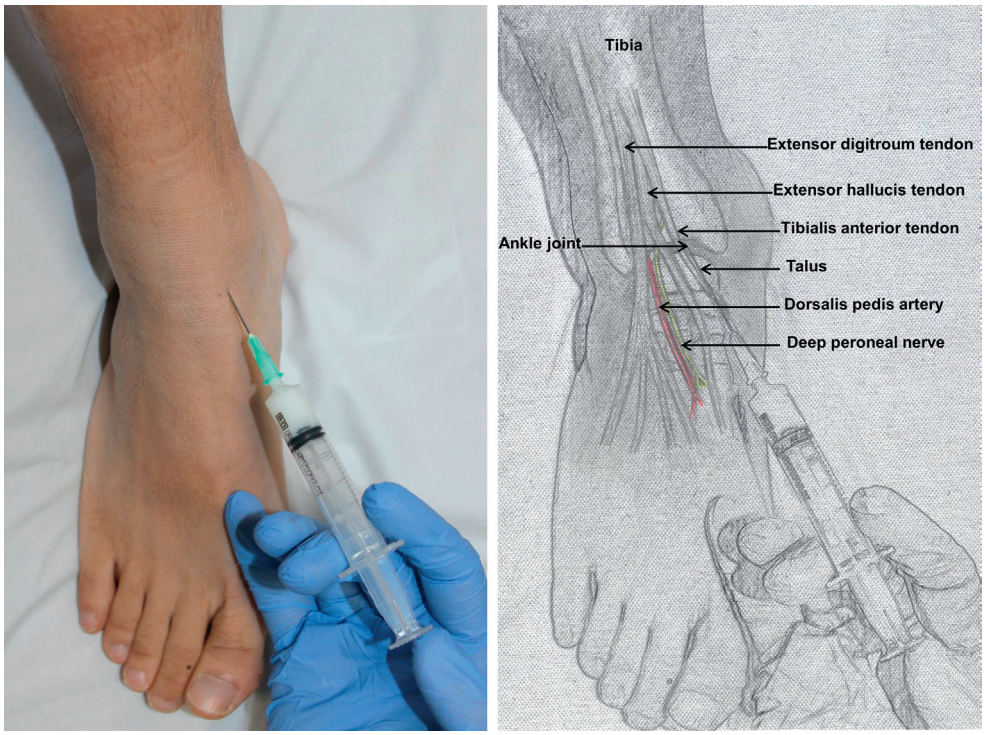

**Figure 54-9** Ankle (talotibial) joint injection.

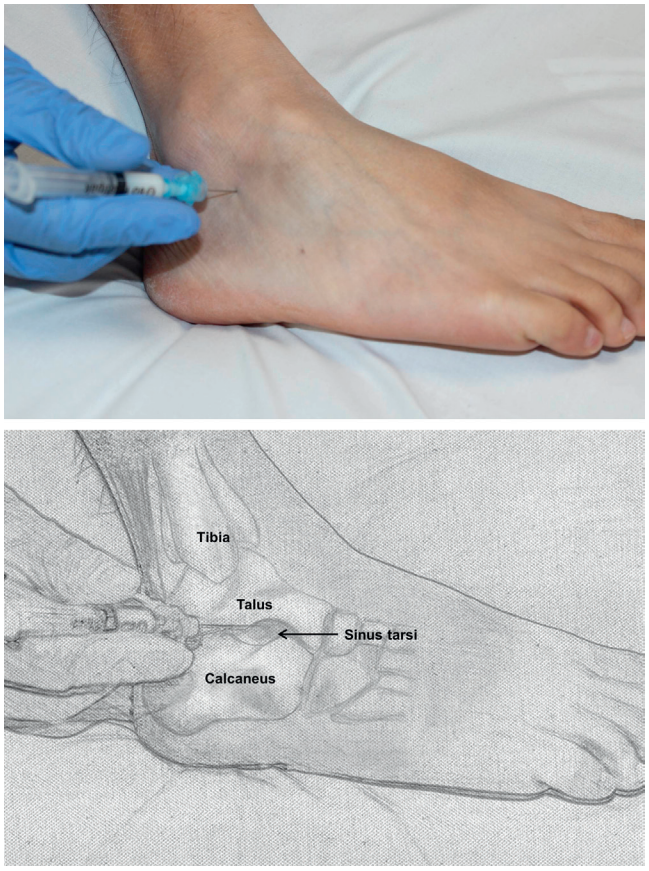

**Figure 54-10** Subtalar joint injection.

**TABLE 54-5** Considerations for Possible Septic Arthritis

| |
|---|
| Sometimes in septic arthritis, gout, or hemoarthrosis, the pus or synovial fluid can be very thick and therefore difficult to aspirate; in this case, use larger-bore needles and/or ultrasound guidance to allow the withdrawal of the knee content. |
| If no fluid is obtained and an infected joint is strongly suspected, consider injecting the joint with saline (lavage) and re-aspirating. |

2. Palpate either the lateral or medial border of the patella. Identify the point at which the proximal one-third meets the distal two-thirds. Insert the needle under the patella in a slightly cranial position toward the SPP, just proximal to the upper pole of the patella (Figure 54-11). Aspirate and then slowly inject the syringe. Follow the general postinjection care steps.

For Baker's cysts, it is preferable to use ultrasound guidance so that the cyst can be easily visualized and the neurovascular structures can be avoided (see Figure 54-4B; Table 54-5).

## SOFT TISSUE INJECTIONS: UPPER LIMBS

### Trigger Finger and Tendon Sheath Injection

Digital flexor tenosynovitis is a common condition associated with inflammatory arthropathies and occasionally with OA. If the tendon sheath is thickened, it may lead to triggering. However, patients with tenosynovitis can be seen with swelling and pain of the finger that can be mistaken for joint synovitis or dactylitis. Use of ultrasound for diagnosis and procedure guidance is highly recommended.

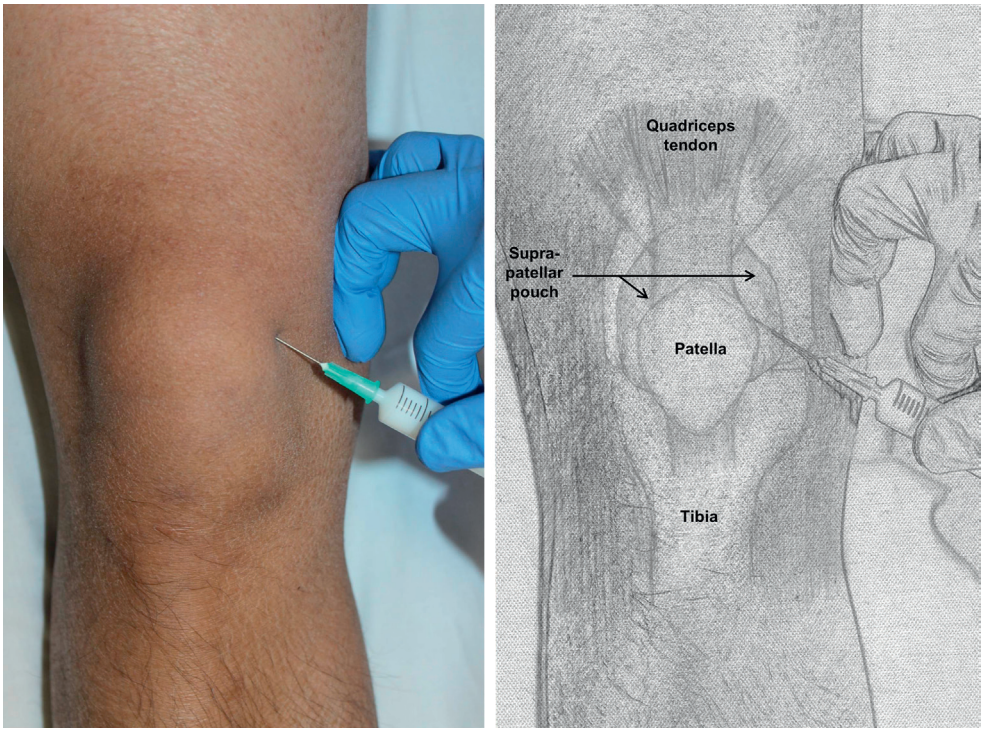

**Figure 54-11** Knee joint injection.

Materials needed are a 25-gauge needle, a 2 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide (5 mg) or hydrocortisone, 25 mg (±1 mL 1% lidocaine).

*The procedure is as follows:*

1. Position the patient's palm facing upward with the fingers extended.
2. Insert the needle with a 30 degree inclination distal to the crease over the MCP joint, and advance it proximally, aiming toward the tendon and reducing the angle between the needle and the skin, to as close to a parallel position as possible (without touching skin).
3. Try to inject generally while advancing. Once the needle is inside the tendon sheath, the resistance to the plunger will disappear.

For an ultrasound-guided procedure, visualize the tendon on longitudinal view (Figure 54-12). Insert the needle from a proximal (or distal) position to the probe, directing it to the region of interest where the whole length of needle can be visualized and the location of injection can be allocated in real time. Proceed as described above.

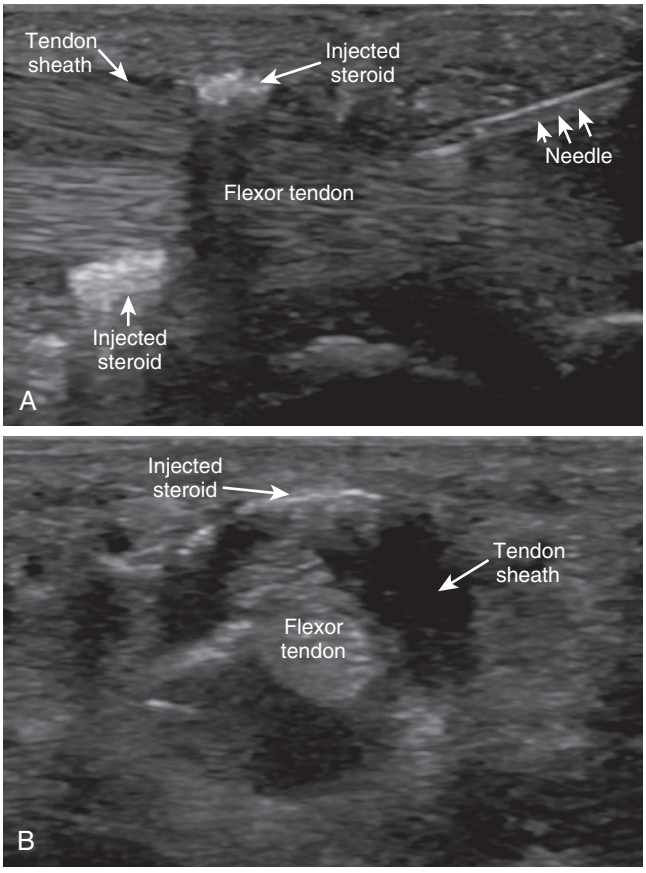

**Figure 54-12** Ultrasound-guided tendon sheath injection. **A,** Longitudinal view. **B,** Transverse view.

## Carpal Tunnel Injection

This procedure can be beneficial in cases of mild to moderate sensory carpal tunnel syndrome that do not respond to conservative therapies such as splints. It can also be indicated when surgical release cannot be done because of long wait times or patient preference. The median nerve lies below the palmaris longus tendon, which can be used as a landmark for this procedure. The clinician can visualize the palmaris longus tendon by asking the patient to oppose the thumb and little finger. It is anatomically absent in 14% of the population.[9]

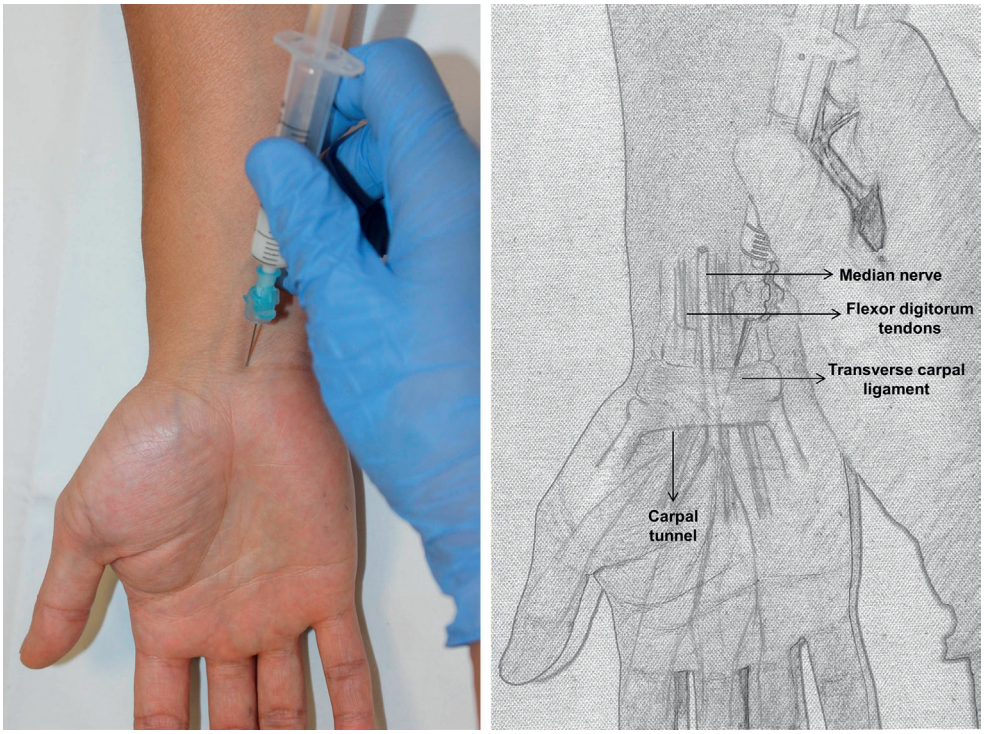

**Figure 54-13** Carpal tunnel injection.

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide (5 to 10 mg) or hydrocortisone, 25 mg (±1 mL 1% lidocaine).

*The procedure is as follows*

1. Place the patient's palm facing upward.
2. Insert the needle at an angle of approximately 45 degrees at the distal palmar crease toward the index finger and below the palmaris longus tendon (from the ulnar side) (Figure 54-13). If the patient feels any paraesthesia, withdraw the needle slightly and reposition it as it can be an indication of penetrating the median nerve.

For ultrasound-guided procedures, put the median nerve on transverse view. Insert the needle from the ulnar side toward the median nerve. The clinician should be able to visualize the whole length of needle in real time. Be careful not to penetrate the nerve. Inject the corticosteroid close to the median nerve under flexor retinaculum.

## De Quervain Tendonitis Injection

This procedure is indicated for treatment of inflammation of the abductor polices longus and the extensor policis brevis common sheath. This procedure is best performed under direct ultrasound guidance.

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide (5 to 10 mg) or hydrocortisone, 25 mg (±1 mL 1% lidocaine).

*The procedure is as follows:*

1. Locate and mark the tendons by asking the patient to extend and abduct the thumb. With de Quervain syndrome, the tendon sheath can be swollen, which directs the position of the needle.
2. Insert the needle just distal to radial styloid near the base of thumb and advance it proximally along the line of the tendon sheath, directing it toward the radial styloid.

For ultrasound guidance, the approach is similar to the tendon sheath injection described previously.

## Tennis Elbow Injection

This injection can be indicated for lateral epicondylitis (tendopathy of the forearm of common extensor origin) in combination with or after failure of conservative management treatment, such as physiotherapy.

Materials needed are a 23-gauge needle, a 5 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisone, 10 to 40 mg (±1 mL 1% lidocaine).

*The procedure is as follows:*

1. Place the patient in a supine position, with the elbow flexed to 90 degrees and placed over the chest.
2. Locate the most tender point in the common extensor tendon (Figure 54-14). Insert the needle until the bone surface is reached, withdraw slightly, and then inject.

## Subacromial Bursa

This injection can be indicated for treatment of subacromial bursitis, impingement syndrome, rotator cuff tendonitis, adhesive capsulitis, and calcific tendonitis. Both anti-inflammatory effects of steroid and hydrodistension of the capsule and bursa may have roles in relief of symptoms. Relief of symptoms after use of local anesthetics is helpful diagnostically as well.

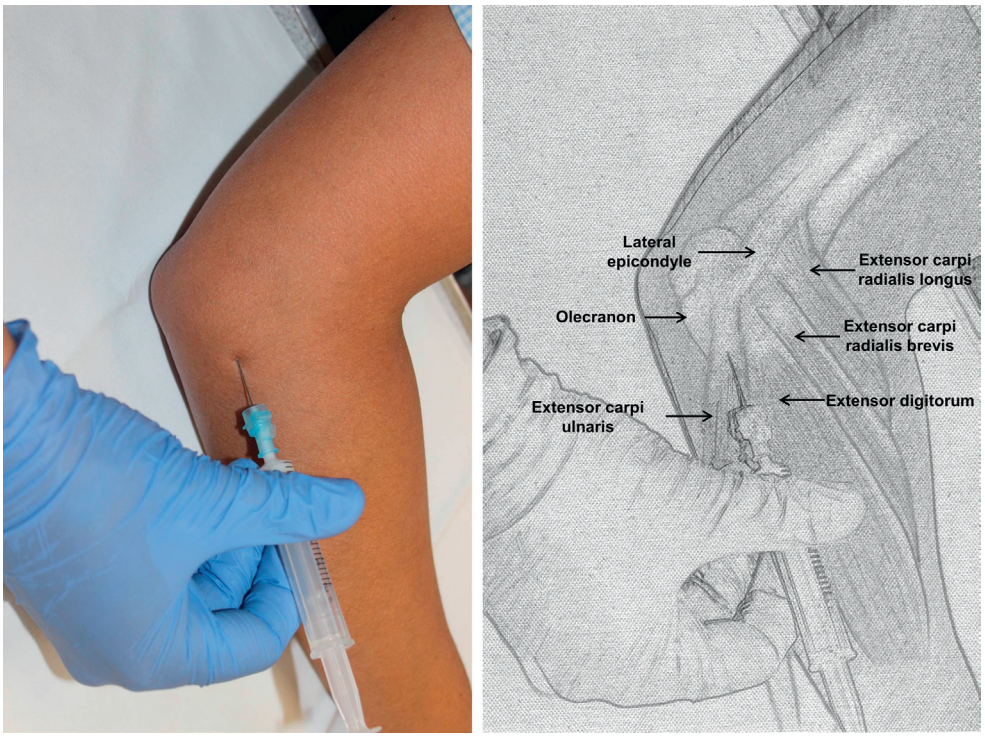

**Figure 54-14** Tennis elbow injection.

Materials needed for the procedure are a 21-gauge needle, a 5 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisone, 20 to 40 mg (±3 mL 1% lidocaine).

*The procedure is as follows:*

1. While the patient's arm is in internal rotation, feel the depression below the acromial process posteriolaterally with your thumb.
2. Insert the needle, aiming to position it slightly anterior and inferior to the acromial process, directing it toward the coracoid process (Figure 54-15). Little or no resistance should be encountered while injecting the plunger because the subacromial bursa has a potentially large space.

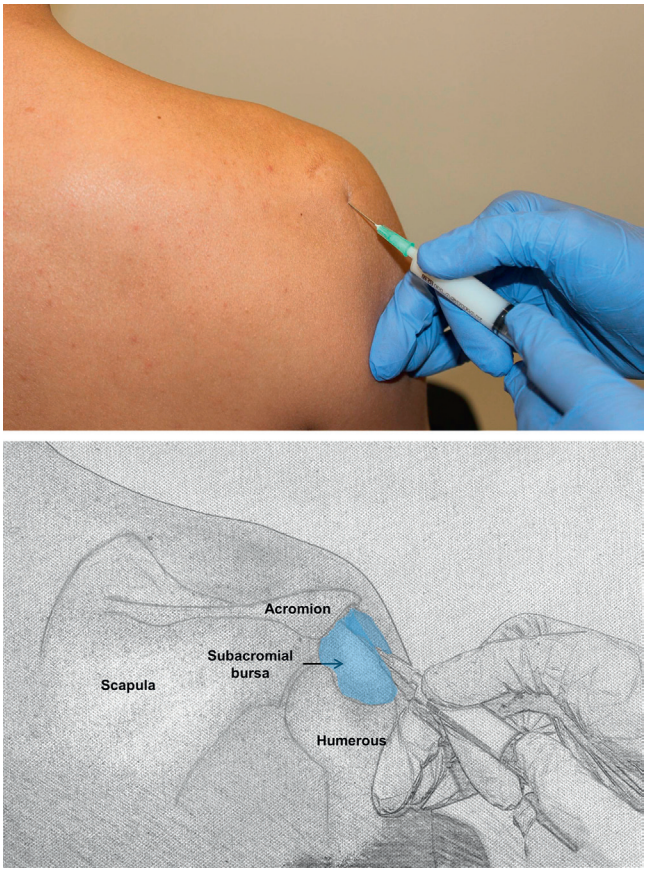

**Figure 54-15** Subacromial bursa.

## SOFT TISSUE INJECTIONS: LOWER LIMBS

### Morton's Neuroma Injection

This is a benign neuroma of an intermetatarsal plantar nerve. Patients are seen with a pain between the third and fourth toes (the most commonly affected area) and/or with a feeling similar to a pebble in the shoe. It can be confirmed with a click sound on MTP squeeze (Mulder's sign) or by ultrasound examination.

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisone, 10 to 20 mg (±5 mL, 2% lidocaine).

*The procedure is as follows:*

1. Palpate and mark the place of entry, which should be halfway between the MTP heads and one-half

inch proximal from the web space from the dorsal side (Figure 54-16).
2. Insert the needle perpendicular to the skin, and advance it through the resistance of the transverse tarsal ligament. A give sensation is felt when the needle passes through the ligament.

## Plantar Fascia Injection

Plantar fasciitis injections are indicated if conservative measures, such as podiatrist interventions (e.g., stretching exercises and insoles), fail. The injection is usually very painful and may lead to fat pad atrophy, which reduces shock absorption. For this reason we do not recommend frequent injections or injection of the fat pad directly at the foot base. Rupture of plantar fascia is also a reported complication.

Materials needed for the procedure are a 23-gauge needle, a 5 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisone, 20 to 40 mg (±2 mL, 1% lidocaine).

*The procedure is as follows:*

1. Place the patient in the lateral decubitus position on the affected side, with the lower leg extended and the upper leg flexed at the hip and knee.
2. Palpate the medial calcaneal tuberosity, and mark the maximum tender point. Insert the needle medially perpendicular to the skin and slightly distal to the medial calcaneal tuberosity (Figure 54-17). Advance the needle until it touches the bony surface.
3. Aspirate and then slowly inject the syringe. Follow the postinjection care steps.

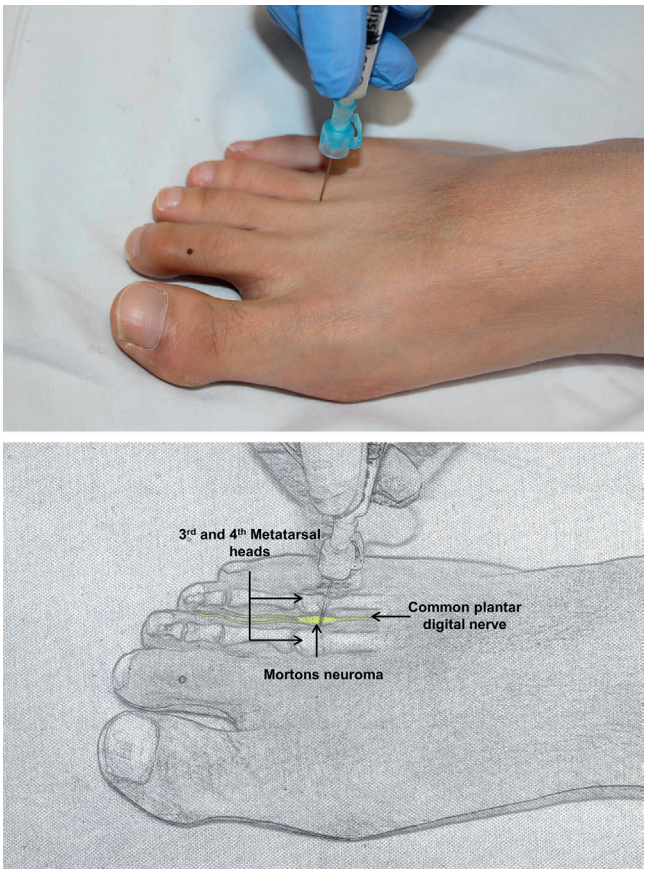

**Figure 54-16** Morton's neuroma injection.

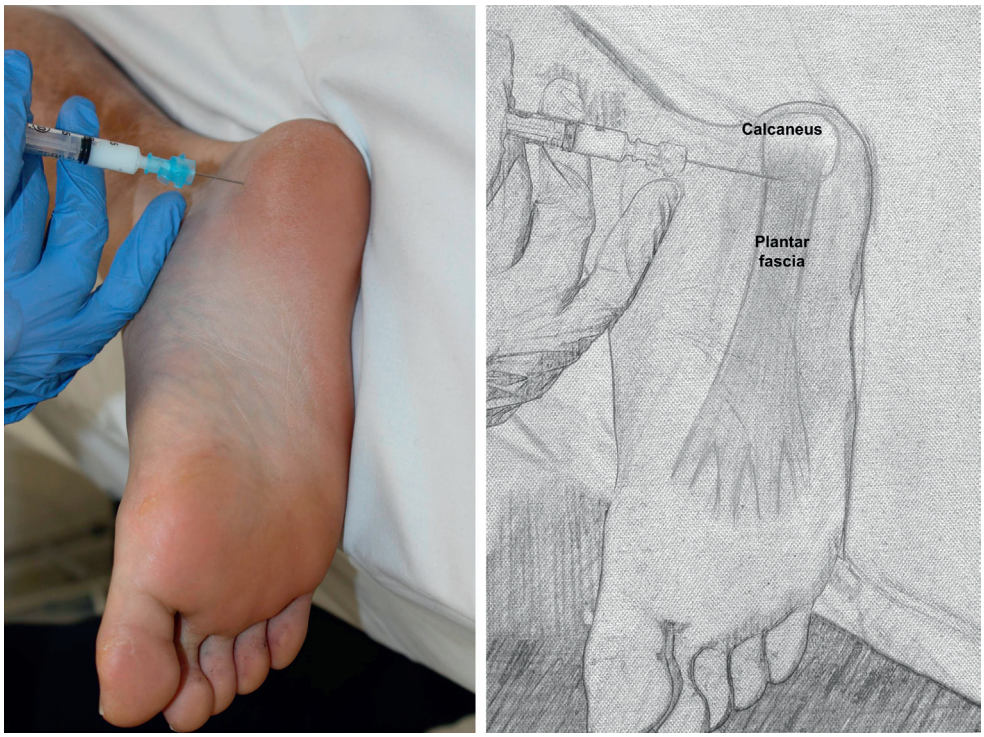

**Figure 54-17** Plantar fascia injection.

For an ultrasound-guided procedure, place the plantar fascia on transverse view at the area just distal to the calcaneal tuberosity. Insert the needle from the medial aspects where the whole length of needle can be visualized and the location of the injection can be visualized in real time. Proceed as described in the preceding text.

## Retrocalcaneal Bursa Injection

This procedure is better performed under ultrasound guidance. However, it still can be done without imaging assistance if ultrasound is not available.

Materials needed for the procedure are a 23-gauge needle, a 5 mL syringe, and a preparation of methylprednisone, 20 mg (±1 mL, 1% lidocaine).

*The procedure is as follows:*

1. Mark the spot in front of the Achilles tendon just proximal to the calcaneus.
2. Insert the needle from the medial or lateral side, perpendicular to the skin at the marked spot for approximately 1.5 cm (Figure 54-18). Never inject against resistance.

For ultrasound-guided procedures, place the Achilles tendon in a transverse view at the area where the retrocalcaneal bursa can be visualized. Insert the needle from the medial or lateral aspects where the whole length of needle can be visualized and the location of injection can be seen in real time. Proceed as described in the preceding text.

## Tibialis Posterior and Peroneal Tendon-Sheath Injection

This procedure is best done under ultrasound guidance. However, a blinded procedure can be performed if swelling of the tendon sheet is very visible and can be identified and injected.

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe (an insulin syringe can be used as well), and a preparation of hydrocortisone, 25 mg/mL.

*The procedure is as follows:*

1. Palpate the medial malleolus and identify the pulsation of the posterior tibial artery. Mark the line of the posterior tibial artery to avoid it.
2. Insert the needle just posterior to the level of the distal end of the medial malleolus (Figure 54-19). The tibialis posterior tendon is the first structure posterior to the medial malleolus (lateral malleoli for the peroneal tendon sheath injection). The needle needs to be directed proximally in a 45 degree angle on an artificial line that extends from the big toe to the heel, following the path of the tendon. Aspirate and then slowly withdraw the syringe. The tendon sheath may form a sausage-like swelling depending on the injection volume. Follow the postinjection care steps.

For ultrasound-guided procedures, use direct visualization of the tibialis posterior (or peroneal) tendons and tendon sheath on longitudinal view and needle inside it before you aspirate and inject. The same anatomic description applies.

## Tarsal Tunnel Syndrome Injection

This injection is indicated for tarsal tunnel syndrome, which is an entrapment of the posterior tibial nerve in the tarsal tunnel. Patients with tarsal tunnel syndrome can be seen with numbness and tingling in the medial third of the plantar area. It can be confirmed with nerve conduction studies.

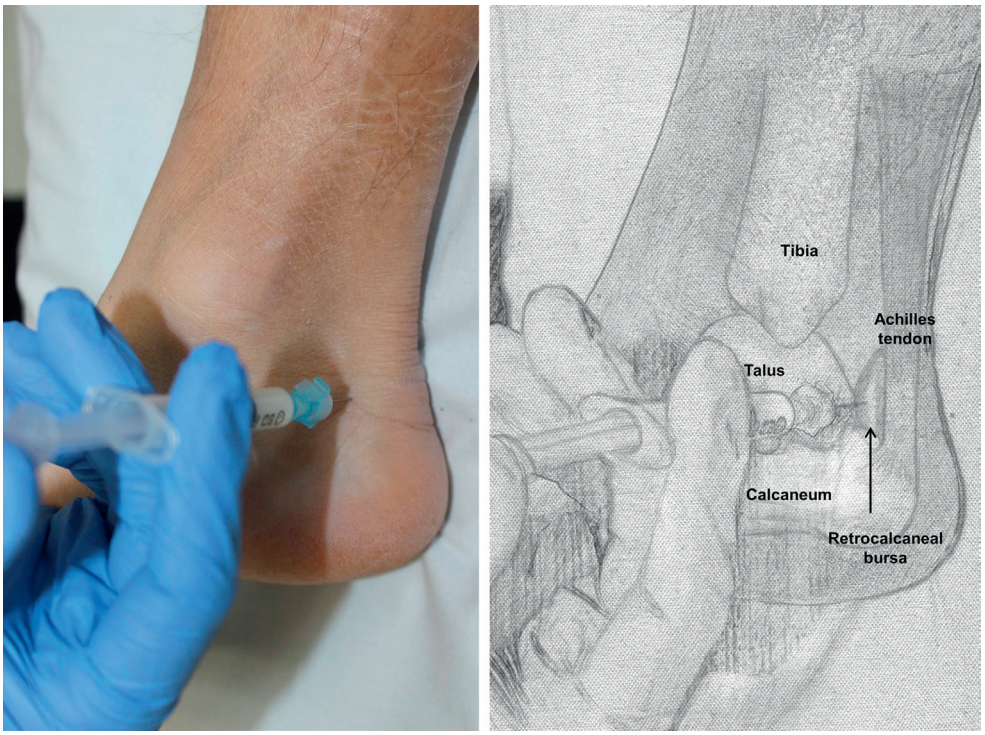

**Figure 54-18** Retrocalcaneal bursa injection.

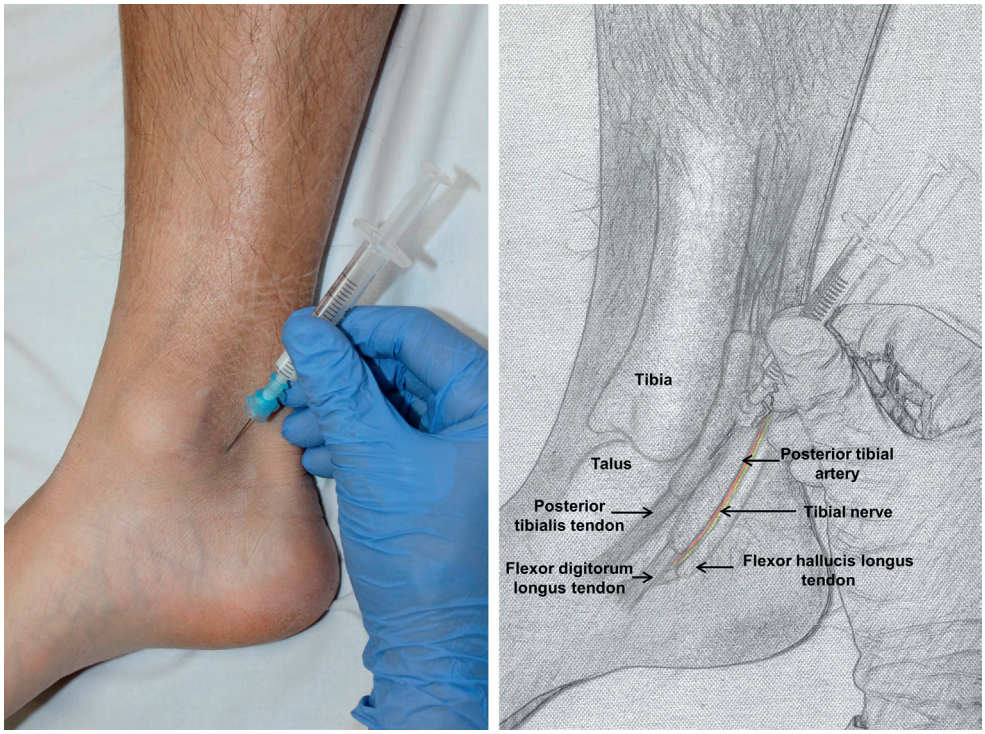

**Figure 54-19** Tibialis posterior and peroneal tendon-sheath injection.

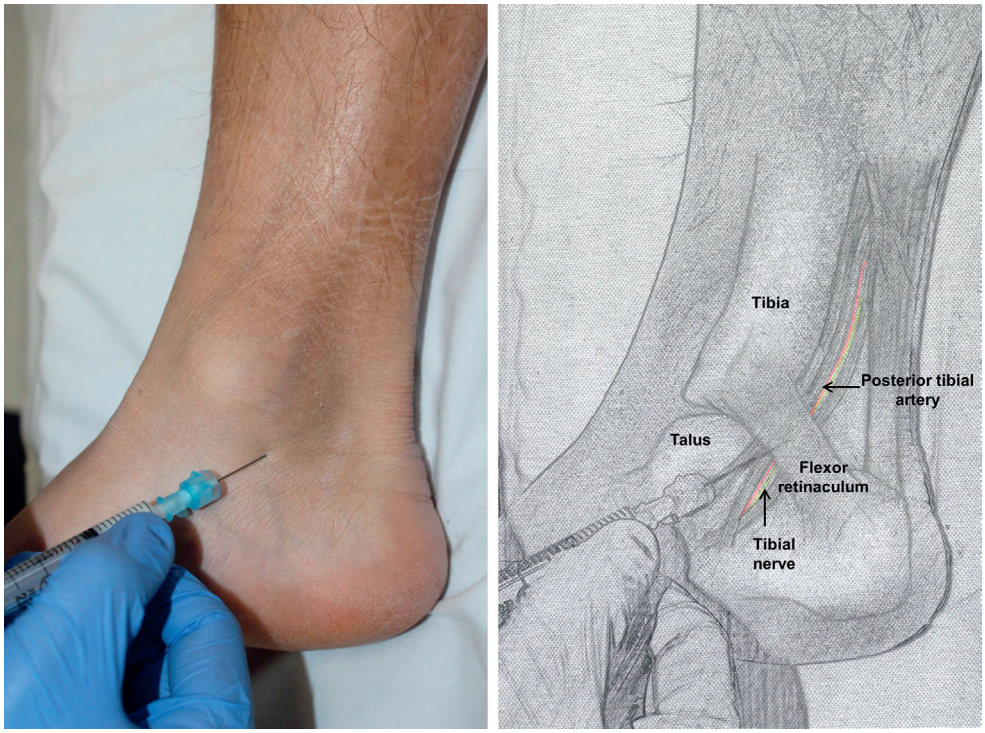

**Figure 54-20** Tarsal tunnel syndrome injection.

Materials needed for the procedure are a 25-gauge needle, a 2 mL syringe (an insulin syringe can be used as well), and a preparation of hydrocortisone, 25 mg/mL.

*The procedure is as follows:*

1. Palpate the medial malleoli and identify the pulsation of the posterior tibial artery. Mark the line of the posterior tibial artery to avoid it.
2. Insert the needle posterior to the medial malleoli and anterior to posterior tibial artery (Figure 54-20). The needle should be inserted parallel to the skin, directing distally in a 45 degree angle on an artificial line extending from the big toe to the heel. Aspirate and then slowly inject the syringe. Follow the general postinjection care steps.

### Trochanteric Bursa

Trochanteric bursitis or greater trochanteric pain syndrome is common, and patients can be seen with hip pain over the greater trochanter area associated with severe tenderness when they lie on the affected side. The greater trochanter can be identified as a bony prominence at the proximal lateral end of the femur.

Materials needed for the procedure are a 23-gauge (long 2-inch) needle, a 5 mL syringe, and a preparation of a longer-acting corticosteroid like triamcinolone acetonide or triamcinolone hexacetonide or methylprednisone, 40 mg (±2 mL, 1% lidocaine).

*The procedure is as follows:*

1. Ask the patient to lie on his or her side, with the affected side facing upward.
2. Palpate and mark the most tender point over the greater trochanter area.
3. Insert the needle perpendicular to the skin until it reaches the hard bony surface, withdraw the needle slightly, aspirate, and then inject. Follow the general postinjection care steps.

## CONCLUSION

Arthrocentesis and joint and soft tissue injections are a key part of rheumatology management with respect to diagnosis and treatment. It can be safe and very effective as long as certain key points are considered. The correct indication, knowledge of anatomy, right technique, and use of correct medications can lead to excellent outcomes. Meticulous documentation, patient education about potential complications, and postinjection care are very important to optimize the procedure outcome. Different techniques can be applied. However, with the introduction of musculoskeletal ultrasound, imaging-guided procedures have become more feasible.

CHAPTER 55

# Anti-nuclear Antibodies

Stanford L. Peng • Joseph E. Craft

## KEY POINTS

- Among the rheumatic diseases, the presence of anti-nuclear antibodies (ANAs) is characteristic of systemic lupus erythematosus (SLE), systemic sclerosis, inflammatory myositis, and Sjögren's syndrome. It is required for the diagnosis of some syndromes, such as mixed connective tissue disease or drug-induced lupus. Fluorescent ANA testing is appropriate as a first screening step when such diseases are clinically suspected.
- Testing of individual ANA specificities should be performed only in the context of clinical signs that correlate with antibody-disease associations (e.g., anti-DNA or anti-Smith [Sm] in the suspicion of SLE).
- Key ANA specificities in SLE include anti–double-stranded DNA, which corresponds to renal disease and overall disease activity; antiribosomal P, which corresponds to neuropsychiatric manifestations and renal disease; anti-Ro/SS-A and anti-La/SS-B, which associate with cutaneous and neonatal lupus; and anti-Sm, which is considered SLE-specific without clear clinical disease manifestation correlations.
- Key ANA specificities in systemic sclerosis include anti-kinetochore (anti-centromere), which corresponds to CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias) manifestations; anti–sclerosis (Scl)-70 (topoisomerase I) and anti–RNA polymerase III, which are associated with diffuse cutaneous disease and pulmonary fibrosis, and accelerated risk of cancer-associated systemic sclerosis; and anti–polymyositis (PM)-Scl (exosome), which is found in myositis–systemic sclerosis overlap.
- Key ANA specificities in inflammatory myositis include anti-synthetase, such as antihistidyl transfer RNA synthetase (e.g., Jo-1), which is associated with the poor-prognosis anti-synthetase syndrome, and anti–Mi-2 (nucleosome remodeling-deacetylase complex), which is associated with dermatologic manifestations.
- Key ANA specificities in Sjögren's syndrome (SS) include anti-Ro/SS-A and anti-La/SS-B, found in mothers of children with neonatal lupus, and antifodrin, which does not seem to have well-documented prognostic ramifications, but, similar to anti-Ro/SS-A and anti-La/SS-B, is observed at high frequency in the disease.
- Although many ANA specificities are generally considered disease or manifestation specific, exceptions are common, confounded by the observation that many autoantibodies are present at low frequencies in healthy people.
- In clinical use, ANA testing is insufficient to establish or refute diagnoses. Rather, it adds weight to diagnoses that rely heavily on other clinical information.

Anti-nuclear antibodies (ANAs) include a wide diversity of autoantibodies directed against multiple intra-cellular antigens, classically consisting of nuclear specificities such as DNA or small nuclear ribonucleoproteins (snRNPs).[1,2] The ANA diseases (Table 55-1) include syndromes characterized by an unusually high prevalence of ANAs, often screened for by the fluorescent anti-nuclear antibody (FANA) test: systemic lupus erythematosus (SLE), systemic sclerosis (SSc), and mixed connective tissue disease (MCTD). The prevalence of ANAs in polymyositis (PM), dermatomyositis (DM), and Sjögren's syndrome (SS) have been reported to be somewhat lower than in the other ANA diseases, but they are often grouped together because they share similar target antigens and presumably similar etiologies. For decades, ANA testing has been an important diagnostic and prognostic tool for these connective tissue diseases (CTDs), and they have become routine assays in the evaluation of patients with suspected rheumatic disease. However, these autoantibodies also arise in a variety of infectious, inflammatory, and neoplastic diseases, as well as in healthy persons, and thus some knowledge regarding their intricacies and the limitations of the assays is required for appropriate clinical application.

## HISTORY

### KEY POINT

- ANAs have evolved from clinical pathologic observations to be tools in the study of cellular biochemical processes.

In the first formal description of an ANA-related phenomenon in 1948, bone marrow specimens from a patient with SLE were found to contain lupus erythematosus (LE) cells, which were subsequently found useful in the diagnosis of SLE and drug-induced lupus, as well as SS and rheumatoid arthritis (RA).[3] LE cells were soon discovered to be attributed to deoxyribonucleoprotein-specific autoantibody, which opsonized and/or induced apoptosis in free-cell nuclei, resulting in antibody sensitization and phagocytosis by polymorphonuclear neutrophils. In 1957, indirect immunofluorescence allowed the development of the FANA as a more sensitive assay for SLE and related diseases.[4] Finer distinction of autoantibody reactivities detected by FANA testing led to the description of Smith (Sm) antigen, nuclear ribonucleoprotein (nRNP), and Ro/Sjögren's syndrome (SS-A) and La/SS-B specificities, which gained further biologic prominence with the demonstration that

**TABLE 55-1** Diseases and Related Conditions Associated with Anti-nuclear Antibodies

| Condition | Patients with ANAs (%) |
|---|---|
| **Diseases for Which ANA Testing Is Helpful for Diagnosis** | |
| Systemic lupus erythematosus | 99-100 |
| Systemic sclerosis | 97 |
| Polymyositis/dermatomyositis | 40-80 |
| Sjögren's syndrome | 48-96 |
| **Diseases in Which ANA Is Required for the Diagnosis** | |

ANA, Anti-nuclear antibody.

Modified from Kavanaugh A, Tomar R, Reveille J, et al. Guidelines for clinical use of the anti-nuclear antibody test and tests for specific autoantibodies to nuclear antigens. American College of Pathologists. *Arch Pathol Lab Med* 124:71-81, 2000.

their autoantigens play prominent roles in cellular homeostasis (Table 55-2). Subsequent investigations have revealed many autoantigens, many of which are still largely uncharacterized. Thus ANAs have not only served as diagnostic markers but also have greatly aided studies on intra-cellular metabolism.

## RELEVANCE OF ANTI-NUCLEAR ANTIBODIES TO DISEASE PATHOGENESIS

**KEY POINT**

**ANAs and their respective autoantigens have been implicated in disease pathogenesis by producing directly toxic or other pro-inflammatory effects.**

Because of the characteristic presence of ANAs among the ANA diseases, ANAs have been speculated to play a role in the pathogenesis of rheumatic disease. For example, it is suspected that anti-DNA antibodies promote inflammation in SLE nephritis via immune complex deposition, direct binding to cross-reactive glomerular antigens, and/or intracellular penetration and induction of cellular toxicity.[5] Similarly, RNP antibodies such as anti-Ro/SS-A, anti-La/SS-B, and anti-Sm have been implicated in the pathogenesis of cutaneous or cardiac manifestations by penetrating live cells and/or binding to exposed antigens in the skin and/or heart.[6] Sera containing anti–sclerosis (Scl)-70 (topoisomerase I) activity can induce high levels of interferon (IFN)-α, correlating with diffuse cutaneous scleroderma and lung fibrosis,[7] and it has been demonstrated that anti–Jo-1$^+$ or anti-Ro/SS-A$^+$ sera from patients with myositis induce type I IFN and/or intercellular adhesion molecule-1 on endothelial cells.[8,9]

However, autoantibodies alone fail to account for disease pathogenesis. Induction of type I IFN activity by anti-Ro/SS-A–containing sera, for instance, appears restricted to patients with SLE or SS, not asymptomatic persons.[10] This phenomenon, interestingly, may reflect additional biologic issues among or effects of the autoantigens themselves, such as novel conformations or epitopes: for example, a proteolytically sensitive conformation of histidyl-transfer RNA (tRNA) synthetase, the target of pulmonary fibrosis–related Jo-1–specific antibodies, has been described in the lung,[11] and an apoptope (i.e., an epitope expressed on apoptotic cells) of Ro/SS-A may be specific to SLE, suggesting a unique role of apoptosis in disease pathogenesis.[12] The autoantigens themselves may have unique biologic functions: 60 kDa Ro/SS-A, for instance, may serve as a receptor for the anti-phospholipid-related β2-glycoprotein I, and this dynamic may account for differences in Ro antibody pathogenicity.[13] In addition, many autoantigens likely have intrinsic pro-inflammatory properties, such as the stimulation of innate inflammation by DNA and RNA via Toll-like receptors (TLRs) 3, 7, and 9 or other intra-cellular nucleic-acid binding receptors,[14] or the induction of smooth muscle responses by the centromere protein CENP-B via CCR3.[15] Interestingly, apparent remission of SLE in a patient has been correlated with loss of TLR responsiveness, antibody deficiency, and disappearance of anti-DNA, supporting such concepts.[16] Thus the pathogenesis of the connective tissue diseases appears to reflect a complex interplay between direct inflammatory or other biologic effects of the autoantigens, as well as the consequences of the autoantibody responses.

## METHODS OF DETECTION

**KEY POINTS**

**The gold standard screening test for ANAs is the fluorescent ANA test.**

**Many antibody tests, including ANA screening in some laboratories, are performed via enzyme-linked immunosorbent assay because it affords higher throughput testing; however, this technique may result in lower accuracy.**

**Optimal clinical interpretation of ANA tests requires knowledge of the technique(s) used in each specific case.**

### Immunofluorescence

The FANA provides a rapid yet highly sensitive screening method for ANA detection and remains the gold standard for initial clinical testing.[17] Here, test sera at varying

dilutions (typically serially increasing by twofold) are incubated with substrate cells, and bound antibodies are detected by fluorescein-conjugated anti-human IgG, followed by visualization via a fluorescence microscope. Results typically are reported by two parameters: pattern and titer, with any pattern of reactivity at a titer of 1:40 or greater considered positive. The former parameter includes one or more morphologic descriptors that typically reflect the localization of the respective autoantigen(s) (see Table 55-2; Figures 55-1 and 55-2). Titer is generally reported as the last dilution at which an ANA pattern is detectable, but such an assessment has been considered somewhat imprecise and subjective, and interlaboratory standardization has not been widely instituted; attempts to standardize the protocol have included computer-based fluorescent image quantification, subjective optical scales, and the use of standardized sera to define international units (IU/mL), which vary by laboratory.

As such, FANA results must always be interpreted in light of the techniques used by the individual laboratory. Cultured cell lines such as HEp-2 cells have remained a gold standard substrate because of their higher concentration of nuclear and cytoplasmic antigens and standardization of use, but some laboratories continue to use heterogeneous substrates, such as rodent liver or kidney tissues, that possess the advantage of eliminating interference from blood-group antibodies, heterophile antibodies, or passenger viruses but may exhibit lower sensitivity of some cell cycle–dependent antigens, such as Ro/SS-A. Additional issues that may contribute to variability in FANA results include differences in reagents and instruments, such as the quality of the fluorescein-conjugated anti-human IgG, specific reference sera, and the microscope used.[18,19]

## Enzyme-Linked Immunosorbent Assay

Enzyme-linked immunosorbent assays (ELISAs) provide highly sensitive and rapid techniques for the detection of autoantibodies. They are commonly used for the detection of specific ANAs, such as anti-DNA and extractable nuclear antigen (ENA) autoantibodies (anti-Sm, anti-Ro/SS-A, anti-La/SS-B, and anti-RNP), often in a "reflex" manner upon detection of a positive screening FANA test. With this technique, test sera are incubated in wells precoated with purified target antigen, and bound antibodies are detected via an enzyme-conjugated anti-human immunoglobulin antibody, followed by color visualization with the appropriate enzyme substrate. The popularity of this technique has further resulted from the commercial availability of ELISA kits and the ability to perform these

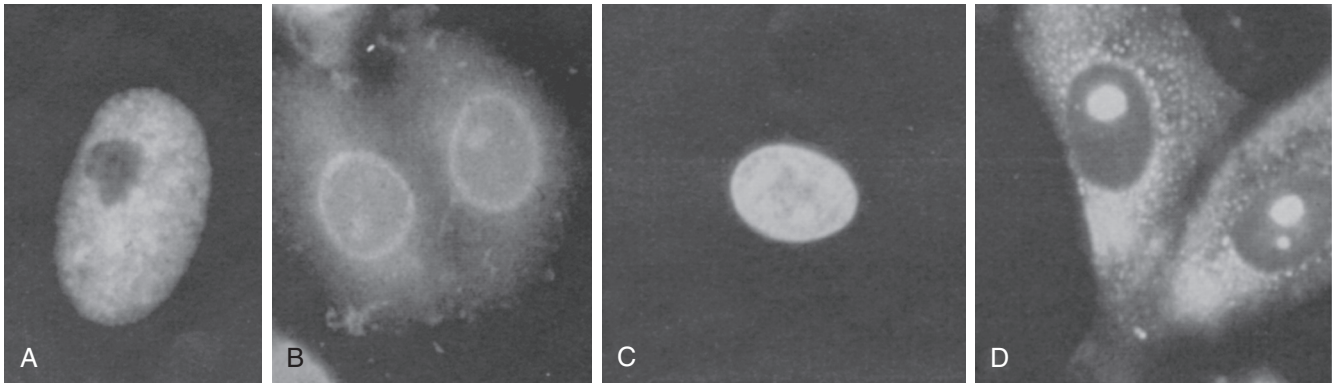

**Figure 55-1** The fluorescent anti-nuclear antibody test: specificities of systemic lupus erythematosus. **A,** Speckled nuclear pattern of anti-Sm antibodies. **B,** Nuclear rim pattern of anti–DNA antibodies. **C,** Homogeneous nuclear pattern of anti-DNA antibodies. **D,** Discrete cytoplasmic and nucleolar pattern of antiribosome antibodies.

(***A,*** *From the Clinical Slide Collection on the Rheumatic Diseases, copyright 1991; used by permission of the American College of Rheumatology.)*

assays on a multiplex platform, enabling large numbers of clinical specimens to be processed quickly at reasonably low cost. As a result, many laboratories also use such solid-phase immunoassays instead of FANA for the screening ANA test; however, this practice is limited by the number of displayed autoantigens (typically 8 to 10), resulting in reduced sensitivity compared with FANA.[20] Conversely, because the ELISA technique can denature autoantigens, ELISAs may produce false-positive results, and confirmation may warrant further testing, which is not always clinically available. Recognition of the local technique used for the detection of ANAs is therefore critically important for their clinical application in diagnosis and/or prognosis.

## Anti-DNA Antibody Tests

Anti-DNA antibodies warrant special consideration because of their wide range of autoantigenic epitopes and their assay difficulties.[5] Antibodies that recognize denatured single-stranded (ss)DNA, which are less specific for rheumatic disease, bind the free purine and pyrimidine base sequences; SLE-specific antibodies that recognize native, double-stranded (ds)DNA bind the deoxyribose phosphate backbone or the rarer, conformation-dependent left-handed helical Z-form. Two methods to ensure the use of native dsDNA in anti-DNA tests include digestion with S1 nuclease, which removes overhanging ssDNA ends, or chromatography on a hydroxyapatite column, which separates ss segments from dsDNA. Unfortunately, despite such efforts, native DNA may spontaneously denature, especially when bound to plastic ELISA plates; this effect may account for some reports of a relative lack of specificity of anti-dsDNA antibodies for SLE.

The Farr radioimmunoassay, which remains the gold standard for DNA antibody testing; involves the binding of autoantibodies to radiolabeled dsDNA in solution. Precipitation of the antibody-DNA complexes by ammonium sulfate allows a quantification of the percentage of incorporated (antibody-bound) radioactive dsDNA. Normal sera typically bind a small fraction of added DNA (usually less than 20%), whereas SLE sera often bind nearly 100% of added DNA. However the specificity of this assay still depends on the quality of dsDNA and the removal of contaminating ssDNA. Also, because of the involvement of radioactivity, the Farr assay is not routinely used in clinical laboratories.

The *Crithidia* test provides an inherently reliable dsDNA substrate that is more often clinically available. Here, the hemoflagellate *C. luciliae* serves as a substrate for indirect immunofluorescence. Its kinetoplast, a modified giant mitochondrion, contains a concentrated focus of stable, circularized dsDNA, without contaminating RNA or nuclear proteins, providing a sensitive and specific immunofluorescence substrate by which to establish anti-dsDNA activity. Thus, together, ELISAs, *C. luciliae* immunofluorescence, and possibly Farr radioimmunoassay tests provide effective, complementary mechanisms to distinguish anti-ssDNA and anti-dsDNA.

### Other Assays

Several additional assays for the determination of ANA specificity include the immunodiffusion and counterimmunoelectrophoresis techniques, two relatively insensitive assays used in many clinical studies associating ANA specificities (especially ENAs) with disease manifestations and outcome; immunoprecipitation and immunoblot, two sensitive and specific assays predominantly confined to research settings; and enzyme inhibition assays (e.g., inhibition of topoisomerase I by anti–Scl-70 and inhibition of RNA splicing by anti-snRNP), which include highly specialized techniques to characterize ANAs functionally.[21] Such assays have not achieved widespread use in clinical diagnostic laboratories because of their cumbersome and/or highly specialized natures.

## INTERPRETATION OF THE FANA

**KEY POINT**

**Although the FANA pattern and titer may provide some insight into the specific autoantigen(s) targeted, as well as the potential likelihood of connective tissue disease, in a given patient, such correlations should only guide, not absolutely determine, clinical decisions.**

### Pattern

Patterns of staining by FANA are often reported as homogeneous, speckled, or rim/peripheral when nuclear staining is present but may also be reported as cytoplasmic, centromere, or nucleolar, reflecting the intra-cellular localization of the target antigen(s) (see Table 52-2; see Figures 55-1 and 55-2). The presence of unusual patterns may be particularly helpful in appropriate clinical settings, such as the presence of a centromere pattern in a patient with features of SSc, suggesting anti-kinetochore antibodies, or a cytoplasmic pattern in a patient with features of myositis, suggesting anti-tRNA synthetase antibodies.[22] However, the presence or absence of patterns is not always highly accurate in predicting specificity, and non-nuclear patterns may not be reported at all by some laboratories, including rare patterns such as nuclear dot, Golgi, or antimitochondrial antibodies, whose clinical significance is uncertain.[23] Furthermore, the role of the FANA pattern in predicting target autoantigen specificities has been largely supplanted in some clinical laboratories by widely available autoantigen-specific ELISAs. As a result, the presence of any such pattern is evidence in an appropriate clinical setting of non–organ-specific autoimmunity, which may warrant further evaluation; however, a specific pattern may only be available and useful in certain cases.

### Titer

Although the widely accepted cutoff for FANA positivity has remained 1:40, greater clinical significance has generally been thought to correlate with higher titers.[18] Healthy persons, usually older and female persons, or relatives of persons with connective-tissue diseases may produce positive FANAs at a frequency sometimes exceeding 30% (see Table 55-1).[24,25] Although these persons often possess titers of less than 1:320 with homogeneous staining patterns, many subjects possess higher titers yet remain clinically asymptomatic for years, and occasional patients with SLE may demonstrate negative FANAs, which perhaps is a more frequent observation if they possess isolated anti-Ro or anti-ssDNA antibodies and/or if the laboratory uses rat or mouse tissues.[26] As a result, the presence of high- versus low-titer FANA results may not be of sufficient clinical significance to warrant differential subsequent evaluation. Rather, a positive screening FANA of any titer requires clinical correlation.

## DISEASES ASSOCIATED WITH ANTI-NUCLEAR ANTIBODIES

**KEY POINTS**

**Key ANA specificities in SLE include anti-dsDNA, which corresponds to renal disease and overall disease activity; antiribosomal P, which corresponds to neuropsychiatric manifestations and renal disease; anti-Ro/SS-A and anti-La/SS-B, which are associated with cutaneous and neonatal lupus; and anti-Sm, which is considered SLE specific without clear clinical disease manifestation correlation.**

**Key ANA specificities in systemic sclerosis include anti-kinetochore (anti-centromere), which corresponds to CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias) manifestations; anti–Scl-70 (topoisomerase I) and anti-RNA polymerase III, which are associated with diffuse cutaneous disease and pulmonary fibrosis; and anti–PM-Scl (exosome), which is found in myositis–systemic sclerosis overlap.**

**Key ANA specificities in inflammatory myositis include antihistidyl-tRNA synthetase (e.g., Jo-1), which is associated with the poor prognosis anti-synthetase syndrome, and anti–Mi-2 (nucleosome remodeling-deacetylase complex), which is associated with dermatologic manifestations.**

**Key ANA specificities in Sjögren's syndrome include anti-Ro/SS-A and anti-La/SS-B, found in mothers of children with neonatal lupus, and antifodrin, which does not seem to have well-documented prognostic ramifications, but, similar to anti-Ro/SS-A and anti-La/SS-B, is observed at high frequency in the disease.**

### Systemic Lupus Erythematosus

ANAs remain a hallmark of SLE; although past studies have reported FANA frequencies as low as 90%, the test is

positive in more than 99% of patients with use of current methods.[27] SLE often evokes autoantibodies against a seemingly endless range of antigens in many cellular locations, but the majority of SLE autoantigens reside in the nucleus and may be broadly categorized into chromatin-associated versus RNP antigens (Tables 55-2 and 55-3), which, interestingly, may facilitate disease subclassification and prognosis.[28]

## Chromatin-Associated Antigens

**Anti-DNA.** Although antibodies against DNA remain one of the most widely recognized specificities in SLE, antibodies against its more physiologic forms—such as nucleosomes or chromatin—are more prevalent in and probably relevant to pathogenesis.[29,30] Nonetheless, most clinical literature remains linked to classic anti-dsDNA antibodies (see anti-DNA antibody tests discussed earlier); many diseases exhibit anti-ssDNA activity, but only SLE sera characteristically possess high-titer anti-dsDNA and/or anti–Z-DNA activity, as characterized by positive Farr or *Crithidia* assays, seen in approximately 73% of patients, in contrast to low titers seen often in SS, RA, other disorders, and healthy persons.[31] In SLE, anti-DNA antibodies strongly correlate with nephritis and disease activity, in contrast to other ANA specificities.[5,31] In some settings, drug-induced anti-DNA antibodies are observed, such as during therapy with some tumor necrosis factor (TNF) inhibitors, although they do not necessarily correlate with clinical manifestations of CTD or response to TNF inhibitor therapy.[32]

Some anti-DNA antibodies may cross-react with other autoantigens, explaining correlation with other end-organ manifestations, such as the neuronal *N*-methyl-D-aspartate (NMDA) receptor or ribosomal P antigens for central nervous system disease.[33,34] Such findings suggest that the immunologically relevant antigen for anti-DNA antibodies may not in fact be DNA. As a result, the presence of anti-DNA activity should always prompt consideration of renal disease, but the presence of anti-DNA activities does not always indicate lupus nephritis, and vice versa. Indeed, in inconsistent clinical settings, anti-dsDNA antibodies likely have low prognostic value.[35]

**TABLE 55-3** Anti-nuclear Antibodies in Systemic Lupus Erythematosus*

| Antibody Specificity | Prevalence (%) | SLE-Specific? | Major Disease Associations |

*Shown are the major anti-nuclear antibody specificities described in systemic lupus erythematosus, along with estimated prevalences and disease associations (***bold*** indicates data supported by multiple studies). See text for details.

CHB, Congenital heart block; dsDNA, double-stranded DNA; LE, lupus erythematosus; PCNA, proliferating cell nuclear antigen; rRNA, ribosomal RNA; SLE, systemic lupus erythematosus; Sm, Smith; snRNP, small nuclear ribonucleoprotein; SR, serine/arginine splicing factors; SS, Sjögren's syndrome; TNF TRs, tumor necrosis factor translational regulators, including T cell intracytoplasmic antigen-1 and TIA-1–related protein.

**Anti-histone (Nucleosome).** Anti-histone antibodies target the protein components of nucleosomes, the DNA-protein complexes that form the substructure of transcriptionally inactive chromatin. They are common in SLE, associate with anti-dsDNA, and are particularly characteristic of and sensitive for drug-induced lupus, where they associate with anti-ssDNA.[30] However, they are commonly seen in other rheumatic diseases, including myositis and SSc, as well as chronic infections, such as Epstein-Barr virus,[21] and as a result, clinical correlations for anti-histone antibodies have not been consistent.

**Other Chromatin-Associated Autoantigens.** Other chromatin-associated autoantigens in SLE include several specificities also observed in other rheumatic and nonrheumatic diseases with still somewhat undefined clinical significance. For instance, autoantibodies against Ku, the catalytic subunit of the DNA-dependent protein kinase implicated in DNA repair and V(D)J recombination, have been associated with a number of clinical manifestations, but only inconsistently.[36] Other chromatin-associated autoantigens include proliferating cell nuclear antigen (PCNA), which participates in a scaffold to facilitate DNA replication, recombination, and repair, and RNA polymerase II, which transcribes some snRNA genes, as well as all protein-encoding genes—both of which remain of uncertain clinical correlation.[21]

### Ribonucleoproteins

**Anti–Small Nuclear Ribonucleoproteins.** In SLE, the most well-described snRNP autoantibodies include the Sm and U1 RNP specificities, which target the RNAs or proteins of the spliceosome, a complex of RNP particles involved in the pre–messenger (m)RNA splicing.[37] These particles include the U1, U2, U4/U6, U5, U7, U11, and U12 snRNPs, each of which consists of its respective uridine-rich ("U") snRNA and a set of polypeptides, including a common core of "Sm" polypeptides (B/B′, D1, D2, D3, E, F, and G), as well as particle-specific polypeptides.[38] Anti-Sm antibodies, which target proteins of the Sm core, the B/B′, and one of the D polypeptides, as well as the Sm-like LSm4, appear in only 20% to 30% of patients with SLE but are considered specific for the diagnosis[39]; however, their presence has only inconsistently been associated with specific disease activity and/or prognosis. In contrast, anti–U1 snRNP (nuclear RNP or U1 RNP) autoantibodies, which target the 70K, A, or C polypeptides specific to the U1 snRNP, occur in 30% to 40% of patients with SLE but are not specific for SLE and likewise have been only variably associated with several disease manifestations.[21,40] Several other snRNP antibodies have been described in SLE, often in overlap syndromes—for example, U2, U5, or U7 snRNP–specific—although their clinical correlations also remain inconsistent.[38]

**Anti-Ro/SS-A and La/SS-B.** The RNP particles anti-Ro/SS-A and La/SS-B, which are part of a macromolecular complex that predominantly processes RNA polymerase III transcripts, often have been associated with SS and the neonatal lupus syndrome, as well as ANA$^-$ SLE (especially anti-Ro: See the previous discussion of FANA). Some, but not all, studies have indicated that anti-Ro may segregate among rheumatic diseases based on subunit specificities; for example, Ro52 without Ro60 specificities correlates with SS, whereas Ro60, perhaps specifically a Ro60 apoptope, with or without Ro52 specificities, correlates with other CTDs, including SLE.[41] In SLE, anti-Ro associates with several manifestations, especially skin disease (cutaneous lupus, chilblains, and photosensitivity) and sicca symptoms, but also the neonatal lupus syndrome, including congenital heart block, anti-La, rheumatoid factor, pulmonary disease, complement (especially C4) deficiencies, thrombocytopenia, lymphopenia, and cardiac fibroelastosis.[21] In comparison, anti-La correlates with late-onset SLE, secondary SS, the neonatal lupus syndrome, and protection from anti-Ro–associated nephritis.[42]

**Antiribosome.** The most well-studied antiribosome antibodies in SLE, antiribosomal P protein (anti-P), target the P0, P1, and P2 proteins of the large 60S ribosome subunit. Although they occur in only a minority of patients, they are considered highly specific for SLE and are particularly specific for neuropsychiatric lupus, classically psychosis.[43] Correlations with active disease, renal disease, liver and hematologic disease, alopecia, anti-Sm, anti-DNA, and anti-cardiolipin antibodies have also been reported.[44] Other less prevalent antiribosomal antibodies target ribosomal (r)RNA, such as the 28S rRNA, or other ribosomal proteins, such as the S10, L5, and L12 subunit proteins, although their clinical significance remains unclear.[45]

**Other ANAs in SLE.** Many other SLE ANA specificities have been described, some of which apparently are quite prevalent, such as the SR splicing factors, proteosome, and TNF translational regulator or RNA helicase A specificities. Many such specificities continue to lack clear clinical context, although preliminary analyses indicate some correlation, such as Ki-67 with sicca or RNA with overlap syndromes. Others remain of interest because of their connection with other diseases, such as perinuclear anti-neutrophil cytoplasmic antigens, topoisomerase I, or kinetochore specificities.[21]

## Systemic Sclerosis (Scleroderma)

ANAs against nucleolar antigens characterize the autoantibody response in SSc. Positive FANAs, sometimes speckled in appearance, appear in up to 97% of sera, although percentages vary depending on the substrate used for detection. Unlike SLE sera, however, SSc sera typically, but not always, contain monospecific autoantibody specificities, targeting such structures as the kinetochore, topoisomerase I, or RNA polymerases (Tables 55-2 and 55-4).[46,47]

### Anti-Kinetochore (Centromere) and Anti-Topoisomerase I

Anti-kinetochore (centromere) and anti-topoisomerase I specificities constitute major diagnostic tools in the subclassification of SSc. Originally named anti-centromere, anti-kinetochore targets at least four centromere (kinetochore) antigens (CENPs) of the mitotic spindle apparatus that promotes chromosome separation during mitosis: CENP-B (the predominant kinetochore autoantigen), CENP-A, CENP-C, and CENP-D. As such, these specificities require mitotically active cells for robust detection, accounting for some ANA$^-$ SSc findings (see the previous discussion

**TABLE 55-4** Anti-nuclear Antibodies in Systemic Sclerosis*

| Antibody Specificity | Prevalence (%) | SSc-Specific? | Mutually Exclusive? | Major Disease Associations |

| NOR 90 (hUBF) | ? | No | | |

*Shown are the major anti-nuclear antibody specificities described in systemic sclerosis, along with estimated prevalences and disease associations (***bold*** indicates data supported by multiple studies). Anti-nuclear antibody specificities whose incidences are thought to be "mutually exclusive" of each other in systemic sclerosis are indicated. See text for details.

CREST, Calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, and telangiectasias; hUBF, human upstream binding factor; MRP, mitochondrial RNA processing complex; NOR, nucleolar organizer region; PM-Scl, polymyositis scleroderma; RNase, ribonuclease; snoRNP, small nucleolar ribonucleoprotein; SSc, systemic sclerosis.

regarding FANA). Their clinical significance has been extensively studied and is heavily associated with Raynaud's phenomenon (RP) and CREST (calcinosis, RP, esophageal dysmotility, sclerodactyly, and telangiectasias), in which up to 98% of patients have anti-kinetochore antibodies. In contrast, anti-topoisomerase I (Scl-70) autoantibodies, which predominantly target the catalytic region of DNA helicase topoisomerase I, generally predict diffuse cutaneous disease with proximal skin involvement—pulmonary fibrosis.[48] However, approximately 40% of all patients with SSc lack either antibody,[49] and a minority (<1%) possess both antibodies,[47] such that, although clinically useful for disease classification and prognosis, they may not be used for definitive diagnoses.

### Anti-RNA Polymerases

Anti–RNA polymerase (RNAP) antibodies, which target the eukaryotic RNA polymerases (see the section on SLE: anti–RNAP), are associated with diffuse cutaneous involvement. Although anti–RNAP II antibodies appear in other diseases, such as SLE or overlap syndrome, and may be associated with other autoantibody specificities against Ku or RNPs, anti–RNAP I and III antibodies appear to be specific for SSc, and they may be useful for the prediction of renal crisis. RNAP III antibodies in particular may predict diffuse cutaneous SSc, including higher skin score, tendon friction rubs, and renal crisis, and are associated with an increased risk of cancer, particularly of the lung.[50,51]

### Anti–Polymyositis Scleroderma

Anti–polymyositis scleroderma (anti–PM-Scl) antibodies target the PM-Scl-75 and PM-Scl-100 components of the exosome, an exoribonuclease complex that regulates rRNA.[52] Responses against PM-Scl-75 alone appear more common among patients with diffuse SSc, whereas overlap syndromes are typically associated with responses against both components.[53] Its presence associates with myositis-SSc overlap without SLE features: 50% of anti–PM-Scl antibody–positive patients have the overlap, whereas 25% of the patients with the overlap have the antibody.[54,55]

### Other SSc-Related ANAs

Several other specificities have been described in SSc with possible prognostic implications, including (1) anti-fibrillarin, which targets a component of the U3 small nucleolar (sno) RNP and may associate with diffuse disease, including internal organ or skeletal muscle involvement or pulmonary hypertension; (2) anti-topoisomerase II, which appears to associate with pulmonary hypertension, as well as localized scleroderma; (3) anti-Th (Th snoRNP, mitochondrial RNA processing ribonuclease [RNase]), which may predict pulmonary hypertension, limited cutaneous disease, puffy fingers, small-bowel involvement, hypothyroidism, and reduced arthritis or arthralgias; (4) antibodies against the nuclear phosphoprotein B23, which appear to associate with pulmonary hypertension and anti-fibrillarin antibodies; (5) antibodies against the RNAP II transcription activator Sp1, which seem to correlate with RP and other signs of undifferentiated CTDs; (6) TNF translational regulator specificities, which may associate with lung involvement; (7) anti-U11/U12 RNP antibodies, which appear to correlate with pulmonary fibrosis; and (8) anti–nucleolar organizer region (NOR) 90 (human upstream binding factor).[56] Other ANAs described in SSc include several specificities characteristically observed in other CTDs, such as histone, Ku, Ro, tRNA, snRNP, and anti-neutrophil cytoplasmic antibody (ANCA), although their clinical relevance in SSc remains unclear.

## Inflammatory Muscle Diseases

Inflammatory muscle diseases comprise a diverse group of illnesses often characterized by autoantibody responses against cytoplasmic antigens. Although between 40% and 80% of patients with polymyositis/dermatomyositis (PM/DM) have positive ANA, as many as 90% of patients with all types of inflammatory muscle diseases have autoantibodies to cellular antigens.[57] Myositis autoantibodies are generally categorized into myositis-specific autoantibodies (MSAs), which are considered exclusive to inflammatory myositis, and those associated with overlap syndromes that include myositis (Tables 55-2 and 55-5).

### Myositis-Specific Autoantibodies

The most well-characterized MSAs include the anti-synthetases, which target different aminoacyl-tRNA synthetases.[58] Some of these antibodies target the tRNA anticodon loop, enabling them to inhibit enzymatic activity. The individual prevalences of these antibodies vary, but their clinical associations remain similar: Although PM appears more commonly with anti–Jo-1, and DM is more common with the other synthetases, these specificities together correlate with the "anti-synthetase syndrome," which includes interstitial lung disease, arthritis, RP, "mechanic's hands," hyperkeratotic lines, sclerodactyly, facial telangiectasia, calcinosis, and sicca, generally with a relatively poor prognosis.[59] Recent studies have suggested that anti–Jo-1 antibody levels may correlate with disease activity, as well as the IFN-γ–inducible chemokines CXCL9 and CXCL10.[60] Nonetheless, other disease associations have been reported that are distinct from the anti-synthetase syndrome; for example, one study has associated anti–threonyl-tRNA synthetase antibodies with fetal loss and severe relapsing myositis.[61] A relatively rare activity, anti-KS, has been described against the asparaginyl-tRNA synthetase in a few patients with interstitial lung disease and inflammatory arthritis or undifferentiated CTD,[62] and PL-7 antibodies may correlate with milder muscle disease.[63]

Other MSAs include specificities against Mi-2, a component of the nucleosome remodeling–deacetylase (NuRD) complex involved in chromatin remodeling and transcription regulation, which associates with DM and dermatologic manifestations such as the "shawl" and "V" signs and ultraviolet light exposure[64]; and Mas, a UGA suppressor serine tRNA that carries selenocysteine ($tRNA^{[Ser]Sec}$). Antibodies against the signal recognition particle, the cytoplasmic RNP that translocates nascent proteins across the endoplasmic reticulum, have been reported to be MSAs that associate with acute, severe, treatment-resistant disease; however, findings of recent studies are conflicting.[65] A few recently described specificities, anti-p155 and anti-p140 (MJ, nuclear matrix protein NXP-2) and anti–CADM-140, may represent novel MSAs and may be useful in the distinction of cancer-associated myositis.[56]

### Myositis Overlap Autoantibodies

The most well-described myositis overlap–associated ANAs include snRNP and PM-Scl specificities. In myositis, anti-snRNP antibodies typically target U1 snRNP, although a few anti-Sm and anti–U2 snRNP specificities have been described (see SLE: anti-snRNP). The former tend to associate with features of MCTD, including SLE-myositis overlap, myositis-SSc overlap, and undifferentiated features (Raynaud's phenomenon, puffy fingers, and arthritis) later progressing to myositis, possibly responding to corticosteroids,[66] whereas anti–U2 snRNP associates with myositis and sclerodactyly, sometimes with SLE, and usually without interstitial lung disease.[38] Anti–PM-Scl antibodies associate with myositis-SSc overlap without SLE features (50% of anti–PM-Scl antibody–positive patients have overlap, whereas 25% of patients with overlap have the antibody), and they also associate with arthritis, DM skin lesions, calcinosis, mechanic's hands, and eczema.[54] Other antibodies associated with myositis in overlap syndromes include several specificities found in other diseases, such as Ku, found more commonly in SLE and SSc, and U3 snoRNP (fibrillarin), which is associated with myositis in SSc, especially of the diffuse type. Several other specificities have also been described in inflammatory myositis, although their clinical significance remains largely undefined (see Table 55-5).[21]

## Sjögren's Syndrome

In persons with SS, reported incidences of positive FANAs range widely, reflecting differences in study populations and disease criteria, and they depend heavily on the inclusion or exclusion of secondary, CTD-related disease, which increases the likelihood and amplitude of positive tests.[67] Thus, although ANA positivity as low as 40% has been reported, many studies report frequencies of 90% to 96%,[68] with a diverse range of autoantibodies, including both ubiquitous (Tables 55-2 and 55-6) and tissue-specific reactivities, such as anti-thyroid, gastric parietal cell, and muscarinic receptor. Such issues hinder interpretation of disease associations and disease specificities of ANAs in SS.

Of the SS ANA specificities, the most well-characterized remain Ro (SS-A) and La (SS-B), two nuclear RNPs involved in RNA metabolism (see SLE: anti-Ro/SS-A and anti-La/SS-B),[69] as well fodrin (nonerythroid spectrin), a cytoskeletal heterodimer composed of α and β subunits that are structurally and functionally similar to erythroid spectrin. Anti-Ro antibodies appear in approximately 40% to 95% of patients with SS, are associated with a number of extraglandular manifestations, including serologic association with anti-La and rheumatoid factor, and, interestingly, may result from genetically linked alternative mRNA processing of Ro.[70] Similarly, anti-La antibodies appear in as many as 87% of patients with SS and are also associated with extraglandular manifestations and serologic association with anti-Ro and rheumatoid factor.[21] Antibodies against α-fodrin have been detected in 64% to 67% of patients,[71] but they are relatively uncommon in other CTDs such as SLE. Preliminary analyses suggest some extraglandular and serologic associations. In contrast, antibodies against β-fodrin have been described in as many as 70% of patients, but clinical associations have not been reported.[72] Several other specificities have been reported in SS in a significant proportion (>3%) of patients, including antibodies against MA-I, a 200 kDa protein localized to the mitotic apparatus in dividing cells (which may be identical to

CHB, Congenital heart block; LE, lupus erythematosus; p-ANCA, peripheral anti-neutrophil cytoplasmic antibody; SS, Sjögren's syndrome.

NuMA); p80-Coilin, an 80 kDa protein associated with nuclear coiled bodies (although this antibody might not be CTD specific); as well as specificities characteristically found in other rheumatic diseases, such as kinetochore and perinuclear ANCAs, although their clinical importance remains uncertain (see Table 55-6).[56]

## Mixed Connective Tissue Disease and Overlap Syndromes

Although overlap syndromes of CTD remain matters of nosological debate, virtually all investigators concur that ANAs are universal in these conditions.[73] Indeed, since the initial formal description of MCTD in 1972, the presence of anti–U1 snRNP antibodies has been consistently required for classification and/or diagnosis, with associated ANA titers typically exceeding 1:1,000 and often 1:10,000.[74] However, several investigations have noted that many such patients experience manifestations, both clinical and serologic, that allow the diagnosis of a defined CTD, such as SLE, RA, SSc, or PM/DM,[75] and therefore the accuracy of specific clinical associations of specific ANAs in "overlap" settings is hindered by issues of disease classification. Therefore, in such instances, it seems most reasonable to base the importance of individual autoantibody specificities upon their primary disease association, despite the lack of definitive, well-codified evidence (e.g., anti-topoisomerase I as predictive of eventual diffuse SSc-like skin disease or pulmonary fibrosis, or anti-dsDNA for lupus-like glomerulonephritis).

## Other Conditions

In contrast to the traditional ANA diseases, the presence of a positive ANA in other diseases remains largely unhelpful for diagnosis, although in RP, juvenile rheumatoid arthritis (JRA), and anti-phospholipid antibody syndrome (APS), it can aid prognosis (see Table 55-1). In RP, a positive result increases the likelihood, from 19% to 30%, of the development of a systemic rheumatic disease, including SLE, RA, and SSc, whereas a negative result decreases the likelihood to approximately 7%, which is often helpful for patient reassurance.[76] In JRA, ANA positivity may predict the development of uveitis,[77] and in APS, it may predict the development or presence of underlying SLE.[78] Other conditions in which ANAs have been found include other rheumatic diseases such as the vasculitides or sarcoidosis; autoimmune diseases such as multiple sclerosis or inflammatory bowel disease; and an ever-growing list of additional conditions, including dermatologic, infectious, psychiatric, neurologic, and cardiovascular diseases.[21]

## CLINICAL UTILITY OF ANTI-NUCLEAR ANTIBODY TESTING

The ANAs encompass a wide range of nuclear, nucleolar, and cytoplasmic autoantigen specificities. Within the ANA diseases, including SLE, SSc, PM/DM, SS, and MCTD, many autoantibodies possess unique rheumatologic associations, but the specificity of these associations has diminished as the sensitivity of clinical studies has increased the detection of these specificities in both rheumatic and nonrheumatic diseases. Consequently, tests for ANAs can greatly aid in the clinical evaluation of patients in the context of their particular disease associations, but these studies retain only an adjunct role in rheumatologic diagnosis.

Figure 55-3 describes an algorithm for the rheumatologic evaluation of a patient for ANAs. In most clinical laboratories, the FANA serves as a screening test, with a positive result often prompting "cascade" testing by the laboratory, ordering physician, or both of ELISAs or other assays for specific autoantibody specificities, such as anti-dsDNA, anti-Ro/SS-A, anti-La/SS-B, anti-RNP, and anti-Sm.[17] A negative or low-titer FANA in the setting of a low clinical suspicion of rheumatic disease usually indicates the absence of significant ANAs and argues against the diagnosis of one of the ANA diseases (see Table 55-1)[79]; however, if the clinical picture strongly suggests CTD, further investigation may involve specific assays for antigens that are often FANA negative, such as Ro, Jo-1, or phospholipids. On the other hand, because some specific ANAs possess diagnostic significance, positive FANA results usually warrant follow-up with specialized assays, but only in the setting of strong clinical suspicion, because the positive predictive value of an ANA in the absence of other clinical signs of CTD is low, in part because ANAs may precede clinical disease by many years,[80] and in part because of the relatively high incidence of ANA in healthy persons.[24] Thus, if SLE features are present, further work may focus on anti-DNA, anti-Sm, anti–U1 snRNP, and anti-Ro antibodies. Similarly, if MCTD, SS, SSc, or polymyositis are suspected, the serum may be tested, respectively, for anti–U1 snRNP; anti-Ro or anti-La; anti-topoisomerase I, anti-centromere, or antinucleoli; or anti–tRNA synthetases. If these tests are negative in the setting of high clinical suspicion, repeat testing at a later date may be warranted because titers of such autoantibodies can fluctuate over time, irrespective of disease course.[81] Positive results in these more specialized assays do not alone signify specific diseases, but rather add weight to diagnoses that should throughout the evaluation rely heavily

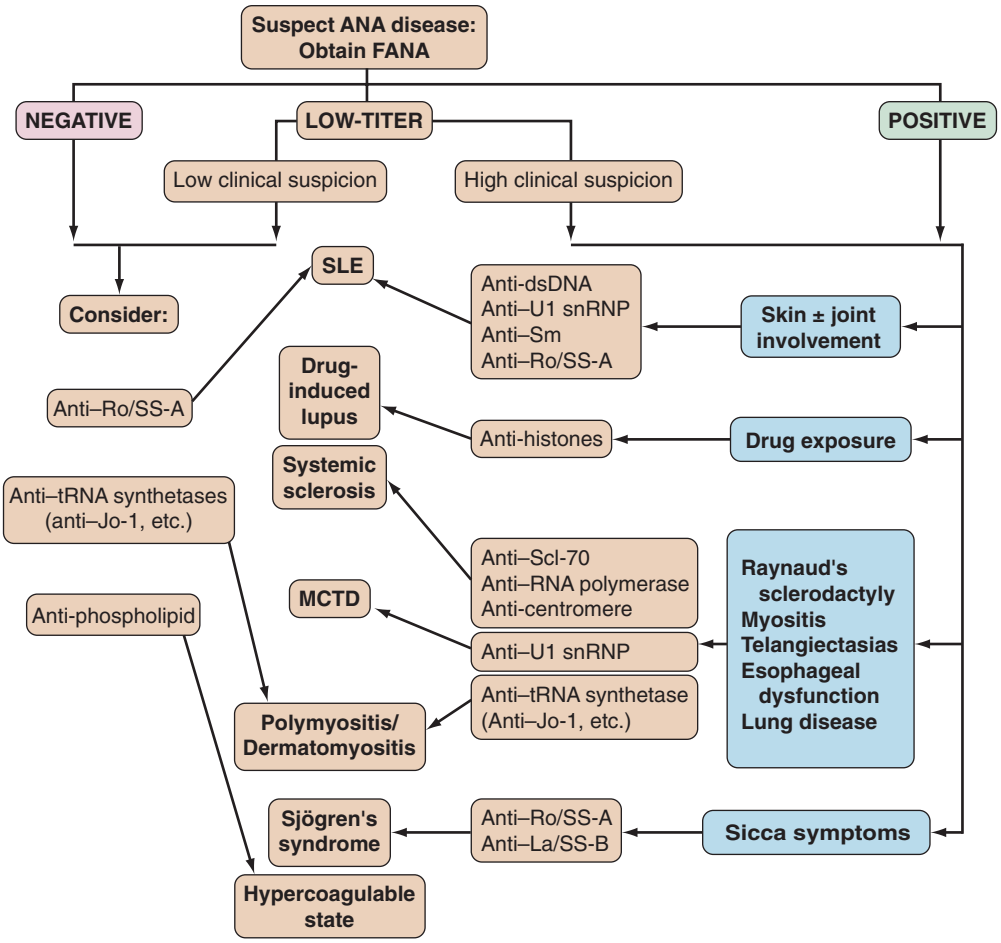

**Figure 55-3** Algorithm for the use of anti-nuclear antibodies (ANAs) in the diagnosis of connective tissue disorders. See text for details. Anti-dsDNA, Anti–double-stranded DNA; anti-tRNA, anti–transfer RNA; FANA, fluorescent anti-nuclear antibody; MCTD, mixed connective tissue disease; SLE, systemic lupus erythematosus; snRNP, small nuclear ribonucleoprotein; SS, Sjögren's syndrome.

on other clinical information. Indeed, many clinical and research studies upon which autoantibody-disease associations have been developed often utilized highly refined detection methods, such as immunoprecipitation or immunoblot, which are often unavailable in routine clinical laboratory testing. Thus the relevance of many antibody-test results in specific clinical settings continues to require careful, individualized interpretation by the referring physician.[82]

CHAPTER 56

# Autoantibodies in Rheumatoid Arthritis

Felipe Andrade • Erika Darrah • Antony Rosen

**KEY POINTS**

- Autoantibodies in rheumatoid arthritis (RA) are important tools for diagnosis and for defining pathogenic pathways in this disease.
- Rheumatoid factors (RFs) are autoantibodies that recognize the Fc portion of immunoglobulin G molecules. They were the first autoantibodies described in RA.
- RFs have numerous causes in addition to RA and therefore have limited specificity for RA.
- Autoantibodies targeting citrullinated proteins are hallmarks of the immune response in RA.
- The anti–cyclic citrullinated peptide (anti-CCP) assay broadly detects antibodies against anti-citrullinated protein antibodies (ACPAs) and has high specificity and excellent sensitivity in RA.
- ACPAs precede the onset of clinical RA and are associated with more severe disease, making them useful as diagnostic and prognostic tools.
- Peptidylarginine deiminase enzymes, which catalyze the conversion of peptidyl-arginine to peptidyl-citrulline, play important roles in generating citrullinated autoantigens in RA.
- Genetic factors such as "shared epitope" human leukocyte antigen–DR subregion alleles appear to interact with environmental factors, such as smoking and infection, to initiate and drive autoimmunity in RA.

Autoantibodies have proven to be very useful tools for diagnosis and prediction in autoimmune rheumatic diseases. Emerging data pertaining to several autoimmune rheumatic diseases have demonstrated that the clinical evolution of disease from the pre-clinical phase to overt clinical disease is marked by a change in the specificity of the immune response, with autoantibodies directed against distinct antigenic targets at different disease phases. Whereas numerous autoimmune rheumatic diseases traditionally have been marked by highly phenotype-specific autoantibody responses (e.g., anti–double-stranded DNA antibodies in systemic lupus erythematosus [SLE] and high-titer anti–topoisomerase-1 antibodies in diffuse scleroderma), the discovery of highly specific autoantibody markers of rheumatoid arthritis (RA) lagged significantly behind these other diseases. During the past decade, enormous progress has occurred in this area, largely fueled by the discovery that citrullinated proteins are specific targets of autoantibodies in RA. This finding has highlighted post-translational modifications (PTMs) as critical determinants targeted by autoantibodies in RA, which has led to the identification of novel autoantibody systems and pathogenic mechanisms in this disease (Table 56-1). In this chapter we will review the autoantibodies in RA, with emphasis on rheumatoid factors (RFs), anti-citrullinated protein autoantibodies (ACPAs), and the anti–peptidylarginine deaminase (PAD) autoantibodies. The implications of these specificities for diagnosis and prediction of outcome, as well as for understanding pathogenic events in the disease, will be highlighted.

## RHEUMATOID FACTOR

The earliest assays (later called the Rose-Waaler agglutination test) that suggested the existence of autoantibodies in RA were developed in the early 1940s, when sera from patients with RA were shown to cause agglutination of sheep blood cells that had been sensitized with subagglutinating doses of rabbit anti–sheep erythrocyte antibodies.[1,2] These assays were later shown to be detecting immunoglobulin (Ig)M antibodies from patients with RA that recognized the Fc portion of IgG.[3] Numerous modifications of the agglutination assay evolved, particularly the use of IgG-coated latex beads instead of sheep erythrocytes.[4,5] Subsequent developments established RF assays in radioimmunoassay, enzyme-linked immunosorbent assay (ELISA), and nephelometry formats, with increased convenience but similar performance in terms of sensitivity and specificity. RFs may be positive in healthy control subjects (1% in younger persons and up to 5% in persons older than 70 years) and in patients with numerous other non-RA diseases (including other rheumatic diseases such as Sjögren's syndrome and cryoglobulinemia), as well as chronic infections.[6-8] The pretest probability of diagnosing RA therefore greatly influences the performance of the RF test, with sensitivities and specificities both in the 50% to 90% range, depending on the patient groups studied.[9,10] The existence of IgG and IgA RFs and evidence of somatic hypermutation have suggested that some RFs in RA are T cell dependent.[11,12] Although some studies have suggested that IgG and IgA RFs increase the specificity of RFs for RA,[13] a recent meta-analysis showed that assays of the different RF isotypes performed very similarly in terms of sensitivity and specificity and therefore do not add much compared with standard RF assays.[14]

Importantly, patients with RA also vary in terms of timing of the appearance of RF, with RF preceding symptomatic disease in a significant subpopulation[15-18] and following disease onset with variable kinetics in other patients.

**TABLE 56-1** Native and Modified Targets of Autoantibodies in Rheumatoid Arthritis

| Type of Antigen | Type of PTM | Antigen Generation | Protein | Prevalence of Autoantibodies |
|---|---|---|---|---|
| Native | None | Unknown | IgG (Fc)<br>hnRNP-A2 (RA33)<br>G6PI<br>PAD4 | 50%-90%<br>35%<br>12%-29%<br>30%-40% |
| Post-translationally modified | Citrullination | Enzymatic reaction mediated by PADs; arginine residues are changed to citrulline | Vimentin, fibronectin, actin, HSP90, histones, α-enolase, eEF1a, CAP-1, CapZalpha-1, asporin, cathepsin D, histamine receptor, PDI, ER60 precursor, ALDH2, collagen type I and II, eIF4GI, aldolase, PGK1, calreticulin, HSP60, FUSE-BP1 and 2, ApoE, MNDA | Up to 80% |
| | Carbamylation | Nonenzymatic reaction of cyanate with lysine residues; lysine is changed to homocitrulline | Unknown | 45% |
| | MAA adducts | Nonenzymatic reaction; peroxidation of membrane lipids generate reactive aldehydes that modify lysine residues, generating MAA adducts | Unknown | 29%-93% |

ALDH2, Mitochondrial aldehyde dehydrogenase; ApoE, apolipoprotein E; CAP1, adenylyl cyclase–associated protein-1; CapZalpha-1, F-actin capping protein alpha-1 subunit; eEF1a, elongation factor 1-alpha; eIF4GI, eukaryotic translation initiation factor-4G1; FUSE-BP, far upstream element binding protein; G6PI, glucose-6-phosphate isomerase; IgG, immunoglobulin G; hnRNP, heterogeneous nuclear ribonucleoprotein; HSP, heat shock protein; MAA, malondialdehyde-acetaldehyde; MNDA, myeloid nuclear differentiation antigen; PAD, peptidylarginine deaminase; PDI, protein disulfide-isomerase; PGK1, phosphoglycerate kinase-1; PTM, post-translational modification.

Indeed, the earlier onset of RF in patients with RA has been associated with more severe disease, highlighting a possible contribution of these antibodies to amplification.[19] The observation that RF only appears after disease onset in some patients suggests that it may mark distinct, sequential events in pathogenesis, which are very close together in the subgroup in whom RF occurs early, or are separated in time in patients in whom RF follows symptoms. The mechanisms that drive the production of RF in persons with RA are not fully understood. The presence of somatic hypermutation in RFs and the evidence that these antibodies are produced by plasma cells in the rheumatoid synovium have suggested that the RF response is driven locally by antigen.[11,12] However, it is still unclear how the IgG becomes self-immunogenic in the rheumatoid joint. In contrast to other autoantigens in RA, there is no evidence that the IgG targeted by RFs requires modification (e.g., PTM) for antibody recognition. Nevertheless, it is still possible that the initial event that breaks tolerance to IgG may be initiated through an abnormally modified molecule, as occurs for other autoantigens in RA. The possible mechanisms whereby RF may play an amplifying role in RA are numerous and include amplification of antigen capture, signaling, and effector functions, among others.[20]

## ANTIBODIES AGAINST CITRULLINATED ANTIGENS

### Antikeratin Antibodies and Antiperinuclear Factor: Initial Insights into a Novel Group of Autoantibodies in Rheumatoid Arthritis

Although RFs have been clinically useful in diagnosis of RA—particularly in cases in which the index of clinical suspicion is high—these autoantibodies have two shortcomings: (1) their lack of specificity for RA and (2) an unclear kinetic and mechanistic connection to pathogenesis. Thus defining additional autoantibodies specific for RA has been a major priority. A significant discovery in this regard was made initially by Nienhuis and Mandema in 1964[21] (Figure 56-1). These investigators recognized an autoantibody that stained keratohyalin granules surrounding the nucleus in cells of human buccal mucosa, which they called antiperinuclear factor (APF). These APF antibodies were found in 49% to 91% of patients with RA,[21-25] and they have reported specificities of 73% to 99%.[21,24-27] The assay was difficult to standardize because not every donor of buccal mucosal cells demonstrated the staining pattern,[28-31] and thus the assay did not find its way into routine clinical practice, but the specificity for RA suggested that the assay might be reporting on a potentially important pathogenic pathway. A second research group subsequently demonstrated that RA sera recognized antigens in the stratified squamous layer of esophageal epithelium—a staining pattern they termed antikeratin antibodies (AKAs).[32] Subsequent iterations of this assay utilized other forms of stratified squamous epithelium, including human skin.[33] Although this AKA assay also had very good specificity properties, it was of limited sensitivity[34-37] and was not particularly convenient or easy to standardize. Thus neither assay was broadly used in the clinical diagnostic arena. Like the LE cell in SLE, however, the assays provided a framework for antigen discovery that would later lead to highly specific and convenient tools for RA diagnosis and classification.

### Discovery of Autoantibodies That Recognize Peptidylcitrulline

The initial discovery of antibodies that recognized keratinized squamous epithelium in patients with RA prompted

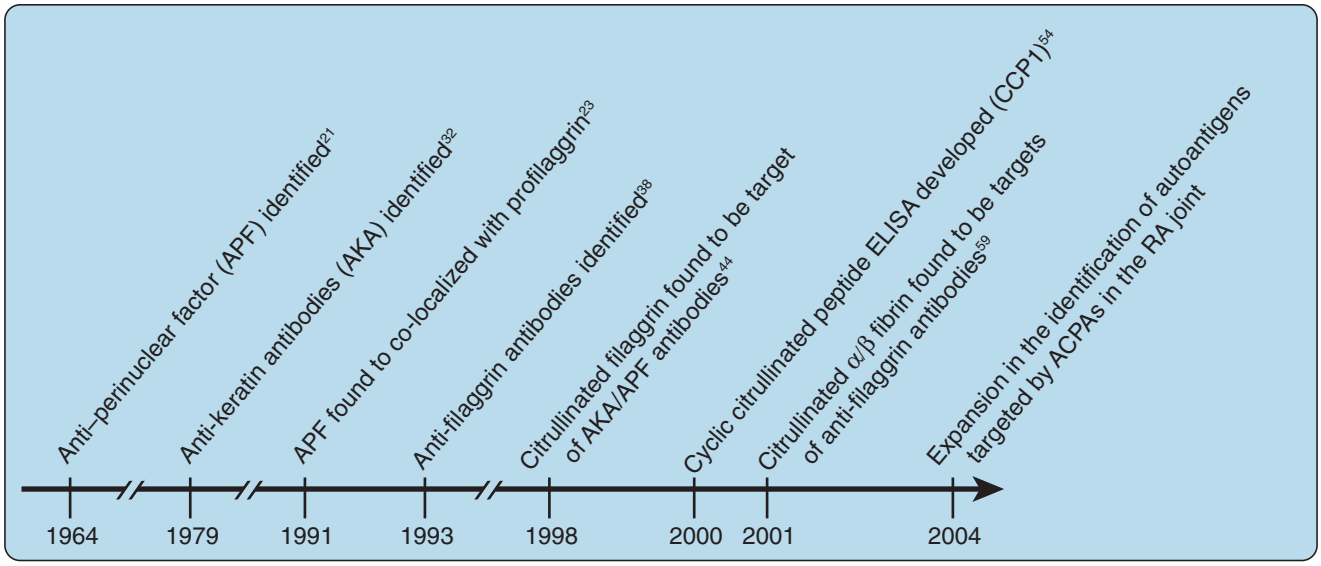

**Figure 56-1** A timeline of the discovery of anti-citrullinated protein antibodies (ACPAs) in rheumatoid arthritis (RA). ELISA, Enzyme-linked immunosorbent assay.

studies to define the target of these antibodies. It was initially shown that APF only stained a fully differentiated squamous epithelial layer and that APF staining was identical to the pattern produced by a monoclonal antibody specific for human (pro)filaggrin in indirect immunofluorescence of permeabilized squamous epithelial cells.[23] Although the antigen could not be definitively identified using this co-localization alone, it suggested that the differentiation state might affect antigen recognition. Subsequently, RA sera were shown to recognize a 40 kDa protein extracted from human epidermis, which was identified as a neutral/acidic isoform of filaggrin.[38] IgG from RA sera affinity-purified against the 40 kDa filaggrin protein was reactive in both the APF and AKA tests, demonstrating that these autoantibodies were very similar or identical.[39]

Filaggrin (filament-aggregating protein) is produced during the late stages of terminal differentiation of epithelial cells. It is synthesized as a heavily phosphorylated precursor protein (profilaggrin) that consists of 10 to 12 filaggrin repeats.[40] Profilaggrin is deposited in granules, and filaggrin is released by proteolytic cleavage during differentiation of the cells by proteases that remain to be fully defined. Coincident with cleavage, the protein is dephosphorylated, and a significant proportion (~20%) of the arginine residues are deaminated (i.e., converted to citrulline),[41,42] a PTM mediated by the PAD enzymes (see later section Citrullinated Antigen Generation in Rheumatoid Arthritis).[43] Because RA sera appeared to specifically target the neutral isoform of filaggrin (which is present and citrullinated in fully differentiated squamous epithelia), van Venrooij and colleagues addressed whether RA sera that were positive in the AKA/APF assays specifically recognized citrullinated peptides.[44] Thus regions within the deduced amino acid sequence of human profilaggrin with a high antigenicity index and the largest number of arginine residues were selected to generate synthetic peptides where arginine residues were substituted with citrulline. Using these citrullinated peptides, van Venrooij and colleagues demonstrated that AKA/APF antibodies are directed against citrullinated filaggrin. It is important to highlight that antibodies against citrullinated proteins in RA do not recognize free citrulline but only citrulline residues (i.e., peptidylcitrullines) within the context of peptides or protein sequences.

These initial studies became the basis for the major discovery that protein sequences containing citrulline residues are one of the most prominent targets for autoantibodies in RA. However, because the epidermis is not a target of rheumatoid inflammation and there is no evidence that (pro)filaggrin is expressed in articular tissues, this molecule cannot be the autoantigen that drives the AKA/APF response in the joint. The fact that anti-citrullinated filaggrin antibodies were enriched in synovial tissue compared with the serum or synovial fluid[45] and that these antibodies are synthesized locally by plasmocytes within the rheumatoid pannus[46] strongly suggests that anti-citrullinated filaggrin cross-reacts with an antigen enriched in the RA joint/synovial tissue. Because citrullination is a very frequent event in different tissues,[47-51] great caution must be exercised when attempting to ascribe a primary role for a specific antigen in driving the antipeptidylcitrulline antibody response. The relevance of filaggrin in RA is therefore largely historic and unlikely to be of pathogenic relevance. Instead, its conformation and high content of citrulline residues make it an excellent surrogate with which to detect antibodies against citrullinated molecules. Many other citrullinated autoantigens found in the rheumatoid joint that are currently being characterized are much more likely to be of pathogenic relevance (see later section Anti-citrullinated Protein Antibodies).

## Anti–Cyclic Citrullinated Peptide Antibodies

In the initial characterization of AKA/APF antibodies, van Venrooij and colleagues used a single C-terminal peptide derived from filaggrin (amino acids 306 to 324) to generate nine variants in which five arginine residues were changed to citrullines, either individually or in pairs, and these peptides were all assayed by ELISA.[44] Interestingly, although

the peptides were almost identical (the only difference being that the citrulline residues had different positions within the peptide), remarkable differences were found in the serum reactivity patterns toward each peptide (from 20% to 48% positivity), suggesting that although citrullination plays a critical role in antigen recognition by AKA/APF antibodies, the modification per se is not the only determinant that confers antibody binding. Instead, the data suggested that AKA/APF represent a pool of antibodies that recognize citrulline residues depending on the context of their surrounding amino acids. Indeed, when data from all peptides were pooled, the sensitivity increased to as much as 76%.[44]

Because peptides often adopt a β-turn conformation within the antibody–peptide complex[52] and cysteine-bridged cyclic peptides have been shown to mimic the β-turn structure of the original antigenic determinant and can bind with enhanced affinity to antibodies,[53] van Venrooij and colleagues engineered a cyclic peptide (substituting the terminal serine residues with cysteines and cyclizing the peptide through the formation of a disulfide bond) to which anti–citrullinated peptide antibodies reacted with higher affinity.[54] Using this cyclic citrullinated peptide (later named CCP1) and its linear counterpart, it was demonstrated that the cyclic structure increased the sensitivity of the assay (68% vs. 49%, without affecting specificity),[44,54] although it was still less sensitive than the assays using the combination of linear peptides (i.e., 76% vs. 68%).[44] Nevertheless, CCP1 became the antigen for the first generation of ELISAs designed to detect antibodies against citrullinated autoantigens.

To improve the CCP1 test, libraries of citrullinated peptides were used to construct the second-generation anti-CCP assay (CCP2), which was broadly adopted for clinical use.[55,56] In 2005, a third generation of anti–cyclic citrullinated peptide (CCP3) was made available for the laboratory diagnosis of RA. These assays have been reported to recognize additional citrullinated epitopes that are not identifiable with the second-generation CCP assays. In studies directly comparing second- and third-generation anti-CCP assays, the assays performed very similarly,[57,58] with a slightly increased sensitivity of CCP3 in some studies (e.g., sensitivities of 82.9% vs. 78.6% for CCP2, with specificities in the 93% to 94% range).[58]

## ANTI-CITRULLINATED PROTEIN ANTIBODIES

The finding that autoantibodies in RA recognize peptide sequences containing citrulline residues and that filaggrin was unlikely to be the physiologic target of these antibodies prompted the search for the primary protein targets of the antibodies detected by the CCP assay. It was believed that the identification of these antigens may provide additional information with regard to patient subtyping (compared with the general anti-CCP assay), as well as novel insights into disease etiology and pathogenesis. With the initial discovery of some of these citrullinated antigens, the name *anti-citrullinated protein antibodies* (ACPAs) was introduced to refer to RA autoantibodies for which detection was performed using citrullinated proteins/peptides from putative RA-associated autoantigens instead of filaggrin-derived or commercial CCPs.

Using protein extracts from rheumatoid synovial membranes and affinity purified anti-citrullinated filaggrin antibodies, Masson-Bessière and colleagues showed that RA synovial tissue contains several citrullinated proteins and defined the α and β chains of fibrin(ogen) as the first local targets for ACPAs in RA synovial tissue.[59] Because circulating fibrinogen is not citrullinated, the presence of citrullinated fibrin in the rheumatoid synovium strongly suggested that after fibrin deposition, citrullination occurs in situ through the activity of locally expressed PAD. This proposal (i.e., that the joint is the site for autoantigen citrullination in RA) has been further supported and extended to many other citrullinated autoantigens in RA.[60]

To date, several different approaches have been used to identify potential ACPA targets in RA. Although these approaches all utilize protein sequencing to identify autoantigens detected by ACPAs using immunoblotting assays, they vary in terms of the source of the antigens. Thus, in addition to RA pannus, identification of citrullinated autoantigens have been extended to rheumatoid synovial fluid, as well as to cell lysates in which purified PADs have been used to generate in vitro citrullinated proteins.

Using these approaches, several citrullinated autoantigen candidates have also been identified. These candidates include vimentin[61,62]; fibronectin[63]; actin[64]; heat shock protein (HSP)90[65]; histones[66]; α-enolase, elongation factor-1α, and adenylyl cyclase–associated protein-1[67]; F-actin capping protein α-1 subunit, asporin, cathepsin D, histamine receptor, protein disulfide-isomerase, ER60 precursor, and mitochondrial aldehyde dehydrogenase[68]; collagen type I[69] and II[70]; eukaryotic translation initiation factor 4G1[71]; aldolase, phosphoglycerate kinase-1 (PGK1), calreticulin, HSP60, and the far upstream element binding proteins (FUSE-BP) 1 and 2[72]; and apolipoprotein E and myeloid nuclear differentiation antigen.[73] Interestingly, some of these molecules (e.g., vimentin, α-enolase, collagen type II, HSP60, aldolase, and calreticulin) had been previously identified as autoantigens in RA, before it was recognized that protein citrullination played a role in their recognition by autoantibodies.[67,74] Although RA sera containing ACPAs may recognize both the native and citrullinated forms of the antigen, the modified form is usually preferentially recognized. Although this group of citrullinated antigens represents proteins that are recognized by RA antibodies, the number of citrullinated proteins found in the rheumatoid joint is more extensive and includes several dozen molecules that have not yet been characterized.[73,75,76] Whether unique ACPAs exist for each one of these molecules or whether only a few citrullinated autoantigens are responsible for driving the complete ACPA response in RA is still unknown.

Among the citrullinated candidate antigens present in the joint, the best characterized clinically and pathogenically are fibrin(ogen), vimentin, collagen type II, and α-enolase. ELISA-based assays have been developed using citrullinated proteins (e.g., fibrinogen) or citrullinated peptides (e.g., vimentin, collagen type II, and α-enolase) derived from these putative RA autoantigens to detect ACPAs. In the case of vimentin, the citrullinated sequence from a mutated isoform isolated from RA synovial fluid (named mutated citrullinated vimentin [MCV]) has been more commonly used instead of the native sequence.[77] Although it was greatly anticipated that the detection of

ACPAs targeting single antigens would provide additional diagnostic information compared with the anti-CCP ELISA, studies in this regard are inconclusive. Thus, in the absence of convincing evidence that measuring individual ACPAs provides any additional information compared with the anti-CCP assay, it appears that the use of CCPs is still a more reliable test to confirm the presence of antibodies against citrullinated proteins. In the case of patients who are anti-CCP negative, the use of antigen-specific assays may provide an additional tool to detect ACPAs.

Because single ACPAs appear to have limited utility in RA, further assays have been introduced to measure more than one ACPA simultaneously. For example, autoantibodies targeting putative RA-associated citrullinated autoantigens are measured using custom Bio-Plex bead-based autoantibody assays (Bio-Rad Laboratories, Hercules, Calif.) in which antigens (usually peptide sequences) are conjugated to spectrally distinct beads.[78] Autoantibody binding to antigen-coated beads is detected with anti–human phycoerythrin–labeled antibody and analysis with a Luminex 200 instrument (Luminex, Austin, Tex.). This assay is slightly more sensitive than the CCP ELISA, detecting ACPAs in approximately 10% of patients negative for anti-CCP antibodies (representing 3.7% of the total patient cohort),[79] a difference that might be explained by the array of peptides used on the assay. In addition, the bead-based multiplex assay has been useful to define the epitope spreading of ACPAs in pre-clinical RA.[78] However, although the multiplex assay provides additional information with regard to unique ACPA specificities present in the patient, knowing these specificities has not yet demonstrated any advantages for diagnosis or prognosis in RA.

## Anti–Cyclic Citrullinated Peptide Antibodies/ Anti-citrullinated Protein Antibodies: Clinical Relevance

The clinical importance of autoantibodies against citrullinated antigens in RA stems from the following favorable features (Figure 56-2):

1. *Anti-CCP antibodies have high specificity for the diagnosis of RA.* In systematic reviews and meta-analyses, anti-CCP antibody positivity has been shown to be as sensitive as but more specific than RF in distinguishing RA from other forms of inflammatory arthritis.[14]
2. *The presence of anti-CCP autoantibodies is an important predictor of development of RA.* RA developed within 3 years in more than 90% of the patients with undifferentiated arthritis who tested positive for anti-CCP, in contrast to only 25% of the patients who tested negative for anti-CCP.[80]
3. *Anti-CCP positivity has been associated with a more severe and destructive disease course, although the independent role of the antibody in comparison with RF has not yet been confirmed.* Some investigators have shown that both RF and anti-CCP antibodies are independent predictors of severity, whereas others have shown that anti-CCP antibodies rather than RF are the better predictor of radiographic progression,[81-88] particularly in patients who were seronegative for RF.[88]
4. *Anti-CCP/ACPAs are associated with RA-related interstitial lung disease (ILD) and cardiovascular disease (CVD).*[89-95] ILD and CVD are extra-articular manifestations with high mortality in persons with RA. Although the mechanistic significance of these associations is still unclear, one possibility is that these antibodies are markers of systemic inflammation that contributes to lung and cardiovascular damage. Alternatively, it is noteworthy that citrullination has been found in lung, myocardium, and atherosclerotic plaque,[51,96-98] suggesting the possibility that these antibodies are directly pathogenic by targeting extra-articular tissues containing citrullinated antigens. The presence of anti-CCP antibodies in patients who have ILD but do not have RA is intriguing and has focused attention on the lung as a possible extra-articular site where RA may be initiated[99,100] (see section Potential Environmental Factors in Rheumatoid Arthritis Pathogenesis).

The early and accurate diagnosis of RA, together with effective treatment with disease-modifying anti-rheumatic

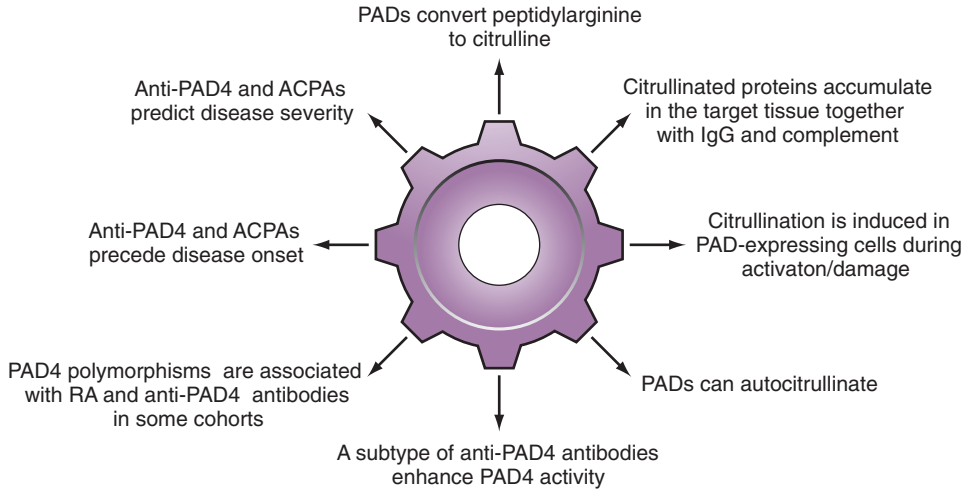

**Figure 56-2** Protein citrullination as a hub in rheumatoid arthritis (RA) pathogenesis. ACPAs, Anti-citrullinated protein antibodies; PAD, peptidylarginine deiminase.

drugs, decreases accrual of joint damage in RA. Because anti-CCP/ACPAs are markers of disease severity and are detectable early in the disease course, they are powerful tools to classify patients with early stage inflammatory arthritis who will benefit from treatment.[101-103]

## Kinetics of Appearance of Anti–Cyclic Citrullinated Peptide Antibodies/ Anti-citrullinated Protein Antibodies in Rheumatoid Arthritis

Recent studies have demonstrated that autoantibodies may precede the onset of clinical disease in both tissue-specific and systemic autoimmune diseases.[17,104-110] Defining events prior to clinical onset is challenging, and several different study designs have been used to define the appearance of autoantibodies and their relationship to disease. The two general categories include (1) stored blood samples collected prior to disease onset (blood banks or military cohorts) and (2) prospective studies examining emergence of autoantibodies and disease in high-risk persons (often relatives of affected individuals).[111] In RA, the former approach has clearly shown that autoantibodies precede RA diagnosis in many persons in whom seropositive RA subsequently develops, often by 2 to 6 years.[109,110,112,113] In several studies, 20% to 60% of patients with RA were RF positive prior to diagnosis, and 30% to 60% of patients were positive for anti-CCP.[109,110,112,113] With one exception,[113] the prevalence of anti-CCP prior to diagnosis was almost twice as high as RF. Interestingly, whereas RF remained present consistently, anti-CCP could vary over time, even disappearing in some persons. In one study, pre-clinical anti-CCP positivity was strongly associated with the development of erosive RA (odds ratio [OR], 4.64; 95% confidence interval, 1.71 to 12.63; $P < 0.01$), whereas RF was not ($P = 0.60$).[113] The evolution of autoantibody epitope spreading in pre-clinical RA has been addressed using a multiplex assay. The study confirmed that ACPA positivity predicts progression to RA in asymptomatic persons and showed that the number of ACPA specificities accumulate over time during the pre-clinical phase of the disease.[78] Moreover, the expansion of the ACPA response precedes the elevation of many inflammatory cytokines, including tumor necrosis factor (TNF), interleukin (IL)-6, IL-12p70, and interferon (IFN)-γ, suggesting that ACPAs may be part of the driving inflammatory process in RA.[78]

Together, these data highlight that the development of autoimmunity against citrullinated antigens is often asymptomatic and generally precedes the onset of clinical disease. This presymptomatic phase is potentially of great importance, because it may identify persons in whom important precursor conditions for the subsequent development of RA have been satisfied. The subsequent events that convert this RA precursor into a chronic, self-sustaining process are not yet known, but defining them is of great importance.

## Genetic Associations with Anti–Cyclic Citrullinated Peptide Antibodies/ Anti-citrullinated Protein Antibodies

Although the association of specific human leukocyte antigen–DR region (HLA-DR) alleles and RA has been known for decades, the relationship between genetics and the development of RA autoantibodies is just beginning to be elucidated.[114] A subset of HLA-DR alleles termed the "shared epitope" (SE) alleles includes HLA-DR*0101, *0102, *0401, *0404, *0405, *0408, *0410, *1001, and *1402 and is united by a conserved sequence of amino acids (QRRAA, QKRAA, or RRRAA) on the alpha helix of the DR-β chain peptide-binding groove.[115] SE alleles are strongly associated with the development of anti-CCP/ACPA but are not independently associated with RF.[80] Furthermore, there appears to be a gene dosage effect on the relative risk of anti-CCP development with an OR of 3.3 to 4.7 for patients with one SE allele and an OR of 11.8 to 13.3 for patients with two SE alleles.[80,116,117] Analysis of individual SE alleles has revealed that anti-CCP/ACPAs are predominantly associated with HLA-DR4 rather than HLA-DR1 SE alleles.[118] Interestingly, smoking has been shown to skew the genetic association of SE alleles with anti-CCP development, with HLA-DR1 and HLA-DR10 SE alleles being more important in this patient group (see Anti-citrullinated Protein Antibodies in Rheumatoid Arthritis: Insights into Disease Mechanism section).[119]

In addition to SE alleles, a single nucleotide polymorphism in the *PTPN22* gene (1858C/T) is also associated with anti-CCP antibodies with an OR of 3.80.[120] *PTPN22* encodes for lymphoid protein tyrosine phosphatase and has been shown to be associated with several autoimmune disorders, including RA.[121] The combination of *PTPN22* 1858C/T genotype and anti-CCP antibodies was 100% specific for RA and confers a relative risk of 130.03. The 1858C/T polymorphism was not associated with RF isotypes and appeared to act independently of SE alleles.[120] Genetic factors such as the SE and *PTPN22* may therefore play a role in the pre-clinical phase of RA, predisposing individuals to the generation of anti-CCP antibodies and susceptibility to the overt disease phenotype.

## Citrullinated Antigen Generation in Rheumatoid Arthritis

### The Peptidylarginine Deiminase Enzymes

Citrulline is not part of the natural pool of amino acids used for protein synthesis, and therefore citrulline residues need to be generated post-translationally once the protein has been synthesized. This PTM, termed *arginine deamination* or *citrullination*, is mediated by the calcium-dependent PAD enzymes. PADs target arginine residues in proteins and mediate hydrolysis of the arginine guanidinium side chain, resulting in the generation of citrulline residues and ammonia (Figure 56-3A). The PADs belong to a larger group of guanidino-modifying enzymes called the amidinotransferase (AT) superfamily.[122,123] This superfamily of enzymes is expressed both in prokaryotes and eukaryotes and includes the arginine deaminases, the dimethylarginine dimethylaminohydrolases, and the dihydrolases.[123] PADs are found in numerous species from bacteria to humans. Interestingly, the bacterial PADs are not dependent on calcium for activity and only contain an approximately 40 kDa catalytic domain, whereas vertebrate mammals have larger multidomain enzymes (~75 kDa) whose activity is regulated by calcium. Five PAD enzymes have been

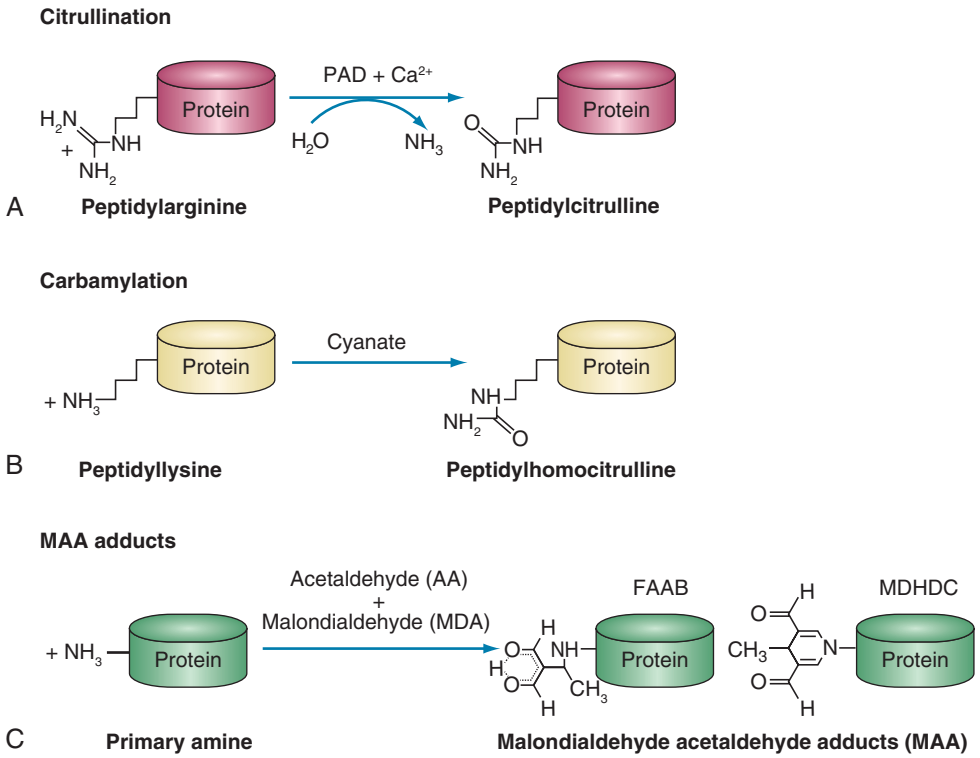

**Figure 56-3** Post-translational modifications targeted by antibodies in rheumatoid arthritis (RA). **A,** During citrullination, the calcium-dependent peptidylarginine deiminase (PAD) enzymes target arginine residues in proteins, resulting in the generation of citrulline residues and ammonia. **B,** Carbamylation results from the reaction of cyanate with the primary amine group of peptidyllysine that is converted to peptidylhomocitrulline. **C,** Malondialdehyde-acetaldehyde (MAA) adducts (FAAB and MDHDC) are generated from the reaction of malondialdehyde (MDA) and acetaldehyde (AA) with primary amine groups of amino acid residues, preferentially peptidyllysine. FAAB, 2-formyl-3-(alkylamino)butanal; MDHDC, 4-methyl-1, 4-dihydropyridine-3,5-dicarbaldehyde.

identified in mammals, and the *PADI* genes are located at a single cluster on chromosome 1p36.1.[43,124] For historical reasons, these isozymes have been designated PAD1 to PAD4 and PAD6. Human PAD4 was initially named PAD5 but was later renamed PAD4 to reflect the fact that it is a true ortholog of this isoform.[125] Although initial evidence suggested that PAD4 was the only nuclear PAD,[126] recent evidence suggests that some PAD2 may also reside in the nucleus.[127]

The PADs are highly conserved and share 50% to 55% sequence identity with each other,[128] with different PADs having distinct substrate preferences and expression in specific tissues. PAD1 is primarily expressed in uterus and skin. PAD2 is more widely expressed in muscle, skin, brain, spleen, secretory glands, monocytes, and neutrophils. PAD3 is expressed in skin and neutrophils, PAD4 is expressed in hematopoietic cells (e.g., neutrophils and monocytes), and PAD6 is broadly expressed in germ cells, peripheral blood leukocytes, lung, small intestine, liver, spleen, and skeletal muscle.[43,61,124,125,129-131] Because of their prominent expression in rheumatoid synovial tissue and fluid,[60,132,133] PAD2 and PAD4 have gained prominence as potential candidates that drive citrullination of self-antigens in RA.

## Peptidylarginine Deiminase Structure, Activity, and Regulation

The three-dimensional structure of PAD4[128,134] and PAD2[135] has been solved and is likely representative of the broader family. PAD2 and PAD4 are dimers formed by head-to-tail contact between the N-terminal domain of one molecule and the C-terminal domain of the second. The N-terminal domain includes two immunoglobulin-like subdomains (named subdomain 1 and 2) that are proposed to mediate protein-protein interactions and/or substrate targeting.[128] Five and six $Ca^{2+}$-binding sites were identified in the structure of PAD4 and PAD2, respectively, with $Ca^{2+}$ binding inducing conformational changes required to generate the active site cleft. Interestingly, the calcium binding residues are highly conserved among PADs, except for PAD6, which lacks some of these sites; the catalytic cysteine is also different in PAD6, and together these findings have suggested that PAD6 is not a deaminating enzyme.

PAD1 to PAD4 rely strongly on the presence of $Ca^{2+}$ for activity and require millimolar amounts of calcium (~2 to 5 millimolar) to be activated in vitro.[136] The resting concentration of calcium in the cytoplasm is normally maintained in the range of 50 to 100 nM and only rises to 200 to 800 nM upon cell activation with physiologic stimuli.[137-140] The large discrepancy between the in vitro and cellular calcium requirements for PAD activation suggests that additional mechanisms, such as allosteric effects of PTMs or partner binding, may regulate PAD activity in vivo by modifying the calcium requirement of the enzyme.[136] It is also important to note that whereas PAD activation provides one level of regulation, the activity of the PADs may also be negatively regulated through autocitrullination. This is not dissimilar to other enzymes, where automodification (e.g., autophosphorylation) modifies enzymatic function. Autocitrullination has been described for PADs 1, 2,

3, and 4.[141,142] In the case of PAD4, direct citrullination of arginines surrounding the active site cleft appears to have major impact on activity and substrate binding.[141] Besides cell activation, it has been proposed that PADs may also be activated under conditions where intra-cellular concentrations of calcium approach extra-cellular concentrations (~1 to 1.4 millimolar), which may occur in dying cells experiencing secondary necrosis or as result of membranolytic damage.[75]

### Structural and Functional Implications of Protein Citrullination

Arginine residues play a central role in the maintenance of secondary and tertiary protein structure. The positively charged guanidino group allows the formation of intramolecular hydrogen bonds to backbone carbonyl oxygens and also intermolecularly between different proteins.[143] During the process of citrullination, the net charge of the protein is reduced by the loss of a positive charge per citrulline residue, producing changes in protein structure and affecting intramolecular and intermolecular interactions.[144]

It is likely that these structural changes also have important functional implications. Indeed, deamination has been implicated in several physiologic processes. In the skin (which expresses PADs 1, 2, and 3[48,130,145]), deamination of filaggrin (a component of the cornified cell envelope) is critical for its degradation into free amino acids, which act as a natural moisturizing factor in the stratum corneum.[48,145] Interestingly, PAD2-deficient mice have normal development and show no abnormalities in the skin,[146] suggesting functional redundancy in mouse development. Whether PAD2 functions in the skin during injury or environmental perturbations is currently unknown. In the immune system, PAD2 (and/or potentially other PADs) citrullinates chemokines, a process that modulates chemokine activity.[147-150] Thus PAD2 may play important roles in controlling effector functions related to environmental triggers.

Human PAD4 (first called PAD5) was first found in human myeloid leukemia HL-60 cells induced to differentiate into granulocytes by retinoic acid[125] and later described in peripheral blood granulocytes.[129] Histones H2A, H3, and H4 and nucleophosmin/B23 were the first PAD4 substrates to be identified.[151] PAD4 appears to function as a transcriptional co-regulator, mediated by its ability to catalyze the deamination of specific residues present in the N-terminal tails of histones.[152-154] This function, together with the finding that PAD4 is expressed during granulocyte differentiation, initially suggested that this enzyme may have a role during granulopoiesis. However, mice deficient in PAD4 have normal development,[155] suggesting that this enzyme has no essential roles in steady-state cellular functions, granulopoiesis, or other developmental processes. Recent studies have demonstrated that PAD4-mediated citrullination of histones is required for neutrophil extra-cellular trap (NET) formation and bacterial clearance,[154,155] suggesting a role for this enzyme in immune and inflammatory effector functions.

PAD6, the most recently defined member of the PAD family, was initially cloned from mouse oocytes and named egg PAD (ePAD),[156] although the enzyme is widely expressed in different tissues. PAD6 is essential for the formation of cytoplasmic lattices, and female mice deficient in PAD6 are infertile but otherwise normal.[131] The function of PAD6 in other organs/tissues besides ovaries is unknown.

### Peptidylarginine Deaminases in Rheumatoid Arthritis

Multiple PADs are likely responsible for autoantigen citrullination in RA, particularly PADs 2 and 4.[60,132,133] Although PAD4 has some unique characteristics that have focused significant attention on this protein, it is important to be aware that no evidence exists to suggest that pathologic citrullination in RA is exclusively or preferentially mediated by this isoform.

It is of interest that several polymorphisms in PAD4 have been genetically associated with RA development, particularly in Asian populations.[157-160] In this regard, two common haplotypes of the *PADI4* gene were initially identified[157] and designated "susceptible" or "nonsusceptible" based on their relative frequency in patients with RA versus control subjects. In the initial population, the OR for the susceptible haplotype was almost 2; this effect was not observed in most white populations. Changes in messenger RNA stability of the susceptible *PADI4* reported in the initial paper were not associated with changes in enzyme level. Furthermore, although the susceptible haplotype generates a PAD4 molecule containing three amino acid substitutions in the N-terminal region (i.e., Gly55-Ser, Val82-Ala, and Gly112-Ala), current evidence suggests that these changes have no effect on the function of the protein.[141,161] Indeed, they appear to affect conformation only within the N-terminal domain but not the active site located in the C-terminal domain.[161] The fact that PAD4 acts as a head-to-tail dimer may nevertheless allow conformational differences in the N-terminus of one molecule to influence the C-terminal domain of another and influence catalysis or even inhibition by autocitrullination. It has been proposed that the PAD4 genotype may exert its effects on RA disease susceptibility as a consequence of its immunogenicity, rather than its enzyme activity.[141] Consistent with this hypothesis is the observation that, in addition to its ability to citrullinate RA autoantigens, PAD4 itself is an RA autoantigen (see next section Anti–peptidylarginine deiminase autoantibodies).[162,163] Moreover, it is noteworthy that the *PADI4* susceptible gene appears to contribute to the development and progression of RA regardless of ACPA status,[164,165] supporting the notion that the snp variant may drive susceptibility through other mechanisms besides the production of citrullinated autoantigens.

## ANTI–PEPTIDYLARGININE DEIMINASE AUTOANTIBODIES

In addition to its prominent enzymatic role in the generation of citrullinated autoantigens, PAD4 itself is targeted by autoantibodies in a subset of patients with RA.[162,163] These antibodies recognize the unmodified form of PAD4, but it has been suggested that autocitrullinated PAD4 may be more immunogenic in some persons.[141] As has been observed for anti-CCP and RF, anti-PAD4 antibodies are frequently present prior to the onset of any disease symptoms.[107] Interestingly, in a cohort of white patients with RA who had established disease, the susceptible PAD4 haplotype was

strikingly associated with PAD4 autoantibodies, even though the association of the susceptible haplotype with RA development has not been observed in white populations.[163] The sensitivity of PAD4 antibodies for RA is in the 30% to 40% range, with a specificity of greater than 95%. PAD4 autoantibodies are associated with anti-CCP antibodies and are independently associated with more severe, erosive RA that persists despite treatment with TNF inhibitors.[166,167] Recently, a subset of anti-PAD4 antibodies identified by their cross-reactivity to the related protein PAD3 has been identified and appears to be the major driver of the previously seen associations with erosive disease severity and progression despite treatment.[136] These antibodies were also associated with anti-CCP antibodies, as well as the SE alleles. Furthermore, patients with PAD3/PAD4 cross-reactive antibodies are at the highest risk for the development of RA-associated ILD, an effect significantly augmented in patients who were past or present cigarette smokers (OR, 61.4).[168] The causal relationship between PAD3/PAD4 antibody development and cigarette smoking is unknown but suggests that environmental factors such as cigarette smoke may trigger the development of RA-associated autoantibodies in susceptible persons (see later section Potential Environmental Factors in Rheumatoid Arthritis Pathogenesis).

## MECHANISMS OF CITRULLINATED AUTOANTIGEN PRODUCTION IN RHEUMATOID ARTHRITIS

Two potential mechanisms have been implicated in aberrant PAD activation and the production of citrullinated autoantigens in the rheumatoid joint. One mechanism involves the hyperactivation of PADs intra-cellularly, and the second relies on extra-cellular autoantigen citrullination. Importantly, these mechanisms are not mutually exclusive but are complementary. Initial immunohistochemical studies of synovial tissue focused attention on synoviocytes and inflammatory cells as potential sources of PADs and citrullinated antigens in the RA joint.[132,133] However, whereas functional studies to address PAD expression, activity, and production of citrullinated autoantigens in isolated synoviocytes are limited and inconclusive,[169] the study of neutrophils has provided important insights into mechanisms of autoantigen citrullination in RA.[64,75,170] These cells represent one of the most abundant cell types in RA synovial fluid and constitutively express several PADs.[64] Furthermore, they can hypercitrullinate and generate citrullinated autoantigens when activated with calcium ionophores,[64] and they are highly enriched in citrullinated autoantigens when freshly isolated from the RA joint.[75] Two mechanisms have been proposed to trigger PAD activation and citrullinated autoantigen production in neutrophils in RA: (1) formation of neutrophil extra-cellular traps (NETs), an antimicrobial system in which granule proteins and chromatin are extruded from the cell and form extra-cellular fibers that bind pathogens,[170] and (2) membranolytic damage mediated by complement or perforin.[75]

During NET formation, PAD4-mediated histone citrullination is important for chromatin unfolding.[171] Activation of PAD4 during this process is believed to result in citrullination of other molecules, resulting in autoantigen generation. Alternatively, it has been proposed that PADs may be released during NET formation, contributing to extracellular citrullination. Although NETs may be an important source of inflammatory signals and some citrullinated autoantigens, the contribution of this process to generating the whole set of citrullinated molecules found in the rheumatoid joint (i.e., the RA citrullinome) is unclear.[170] Instead, recent studies have found that immune pathways that form pores in cell membranes and that are active in the RA joint (e.g., the complement system's membrane attack complex [MAC] and perforin released from cytotoxic cells) are potent activators of PADs and efficient inducers of the RA joint citrullinome.[75] The membranolytic damage induced by these pathways is associated with high intra-cellular calcium flux,[172] which likely explains the hyperactivation of PADs in the damaged cell. It is also possible that other forms of cell death may play a role in mediating enhanced citrullination in the RA joint, particularly if these death pathways (e.g., pyroptosis or necroptosis) result in extra-cellular leakage of PADs. The discovery that fibrinogen is heavily citrullinated in the RA joint provided initial evidence that citrullination can indeed occur extra-cellularly.[59] Furthermore, soluble PAD2 and PAD4 have been detected in the synovial fluid from patients with RA,[60,173] suggesting that these enzymes can gain access to the extra-cellular space during inflammation.

Although the extra-cellular calcium concentration in synovial fluid (0.5 to 1 mM) is more than 1000-fold higher than intra-cellular levels, it is still not optimal for maximal PAD activity in vitro. Recent studies have demonstrated that anti-PAD3/PAD4 cross-reactive autoantibodies are able to enhance PAD4 activity at calcium concentrations found extra-cellularly.[136] These anti-PAD3/PAD4 autoantibodies decrease the enzymatic requirement for calcium into the physiologic range and greatly augment PAD4 activity. Thus PAD4 released by neutrophils during NET formation or other forms of cell deaths may encounter anti-PAD4 antibodies in the synovial fluid with the capacity to activate enzymatic function, contributing to extra-cellular citrullinated autoantigen generation in RA.

## NOVEL POST-TRANSLATIONAL MODIFICATIONS TARGETED BY ANTIBODIES IN RHEUMATOID ARTHRITIS

### Anti–Carbamylated Protein Antibodies

Proteins that contain homocitrulline (i.e., carbamylated proteins) recently have been recognized as an important target of autoantibodies in RA, with IgG and IgA antibodies recognizing carbamylated antigens identified in more than 40% of patients with RA.[174] In contrast to citrullination, carbamylation is a nonenzymatic PTM in which homocitrulline is generated by the reaction of cyanate with the primary amine of lysine residues (Figure 56-3B). Carbamylation therefore accumulates in conditions that enhance cyanate levels, such as uremia, inflammation, and cigarette smoking.[175] In RA, inflammation is likely the most important source of carbamylated proteins. Here, myeloperoxidase (MPO) released from neutrophils promotes the conversion of thiocyanate to cyanate, further enhancing carbamylation.[175,176] Although homocitrulline structurally

resembles citrulline (homocitrulline is one methylene group longer), the finding that anti–carbamylated protein (anti-CarP) antibodies are present in approximately 35% of ACPA⁻ patients and that these antibodies are predictive of a more severe disease course independent of ACPA status has suggested that these antibodies are not cross-reactive between the two PTMs.[174] Moreover, anti-CarP antibodies appear many years before the diagnosis of RA and predict the development of RA independent of anti-CCP antibodies in patients with arthralgia.[177-179] Despite the growing interest in anti-CarP antibodies, a major caveat is that their primary protein targets in RA are still unknown. Indeed, carbamylated–fetal calf serum and carbamylated-fibrinogen are used as surrogate antigens for anti-CarP detection. Furthermore, carbamylated proteins have not yet been described in the RA joint.

### Anti–Malondialdehyde-Acetaldehyde Adducts Antibodies

Malondialdehyde-acetaldehyde (MAA) adducts are the most recently described target of anti-PTM antibodies in RA.[180] Similar to carbamylation, the generation of MAA protein adducts is nonenzymatic and involves the preferential modification of the primary amine of lysine residues. During oxidative stress caused by a variety of stimuli, including inflammation and exposure to alcohol, reactive oxygen species (ROS) trigger peroxidation of membrane lipids, resulting in the formation of malondialdehyde (MDA) and acetaldehyde (AA),[181-184] which react with proteins, resulting in the formation of stable MDA-AA protein adducts, referred to as MAA (Figure 56-3C).[185,186] These adducts have been implicated in contributing to inflammation and cellular injury associated with cardiovascular and alcoholic liver disease.[181-183] Interestingly, RA synovial tissue, but not tissue from patients with osteoarthritis, is enriched in MAA-modified proteins, and patients with RA have antibodies targeting this modification when they are detected using MAA-modified albumin as a surrogate antigen.[180] Whereas anti-MAA antibodies are strongly associated with anti-CCP and RF, it is interesting that anti-MAA antibodies of the IgG isotype are found in 88% of anti-CCP⁻ patients, suggesting that these may be useful biomarkers, particularly in persons with ACPA⁻ RA. However, whether this antibody system is clinically relevant in RA remains to be defined. In this regard, it is important to highlight that anti-MAA adduct antibodies are not specific for RA but have also been found in patients with alcohol-induced liver disease, diabetes, and CVD.[187-189] Therefore these antibodies may not exclusively be markers of joint damage but may be generated as a result of comorbidities associated with RA. Similar to carbamylation, the primary targets of anti-MAA adduct antibodies in RA are not yet known.

### Anti-citrullinated Protein Antibodies, Anti–Carbamylated Protein, and Anti–Malondialdehyde-Acetaldehyde Antibodies in Rheumatoid Arthritis: Insights into Pathogenesis

The finding that persons with RA have antibodies targeting different PTMs is intriguing and unlikely to be accidental. Because neutrophils produce all components (i.e., PADs, MPO, and ROS) required to generate the current set of modified autoantigens in RA (i.e., ACPAs, anti-CarP, and anti-MAA), it has been suggested recently that these distinct antibody systems may indeed represent markers of a common pathogenic event driven by neutrophils, potentially placing these cells at the center of autoantigen production in RA pathogenesis.[190] Confirming this hypothesis would have important implications for future anti-neutrophil therapies in this disease.

## OTHER AUTOANTIBODY SPECIFICITIES IN RHEUMATOID ARTHRITIS RECOGNIZING NONMODIFIED AUTOANTIGENS

Anti-RA33 antibodies were discovered in 1989 as a novel autoantibody specificity recognizing a nuclear protein with an apparent molecular mass of 33 kDa.[191] These autoantibodies initially were detected in 35% of patients with RA but also were detected in a small number of patients who had other autoimmune or degenerative rheumatic disorders. The antigen was termed RA33, and it was the first description of a nuclear antigen apparently specific for RA. Later, the antigen was identified as the A2 protein of the heterogeneous nuclear ribonucleoprotein complex (hnRNP-A2).[192] Further characterization of this antibody showed that it was not strictly specific for RA but was also found in approximately 20% of patients with SLE and in 40% to 60% of patients with mixed connective tissue disease (MCTD).[193,194] However, in SLE and MCTD, they usually occur together with antibodies to U1–small nuclear ribonucleoproteins (snRNPs) or Smith (Sm) antigen. Therefore anti-RA33 without concomitant anti–U1 snRNP autoantibodies were found to have specificity of 96% for RA.[193] Additionally, anti-RA33 antibodies in RA, SLE, and MCTD are distinguished by their recognition of different conformation-dependent epitopes in hnRNP-A2.[195] Interestingly, despite their limited specificity, in the absence of RF and ACPAs, anti-RA33 antibodies in patients with very early arthritis (<3 months' duration) are associated with a relatively mild nonerosive disease course, potentially identifying patients with a good prognosis who will respond well to treatment with disease-modifying anti-rheumatic drugs (DMARDs).[196] In studies in human samples, stimulation assays using hnRNP-A2–induced T cell proliferation in almost 60% of the patients with RA, but only 20% of the control subjects, with substantially stronger responses observed in patients with RA.[197] Interestingly, immunohistochemical analyses revealed pronounced overexpression of hnRNP-A2 in synovial tissue of patients with RA, placing the antigen at sites of disease in RA.

Another autoantigen of potential interest in RA is glucose-6-phosphate isomerase (G6PI). Arthritis in the K/BxN mouse model results from pathogenic immunoglobulins that recognize G6PI,[198-200] a glycolytic enzyme residing in the cytoplasm of all cells. Moreover, antibodies directed against G6PI can, alone, transfer arthritis to healthy recipients.[201] The pathogenic potential of this antibody prompted its study in human RA. However, although initial studies reported a high frequency of such antibodies in sera of patients with RA,[202] these results have been the subject of debate.[203-205] Overall, anti-G6PI antibodies in patients with

RA range between 12% to 29% in different cohorts, with a higher prevalence in patients with active disease. Patients with psoriatic arthritis, undifferentiated arthritis, and spondylarthropathy also displayed anti-G6PI antibodies at similar frequencies (12% to 25%), and similar titers are detected in a proportion (5% to 10%) of control subjects or patients with Crohn's disease or sarcoidosis.[205] The potential relevance of these antibodies in RA is still uncertain.

## ANTI-CITRULLINATED PROTEIN ANTIBODIES IN RHEUMATOID ARTHRITIS: INSIGHTS INTO DISEASE MECHANISM

Although our understanding of the pathogenesis of RA remains incomplete, current models employ a similar construct to other autoimmune rheumatic diseases—that is, in the setting of a complex genetic predisposition, environmental and stochastic events function to initiate an autoimmune process recognizing specific self-antigens, where the immune response itself participates in immune amplification and tissue injury (Figure 56-4). The striking association of RA (and particularly ACPAs) with particular class II major histocompatibility complex (MHC) alleles underscores at least one component of this framework. Whether RA autoantibodies are directly pathogenic or whether they are markers of inflammation and/or damage remains uncertain, particularly for RFs. However, ACPAs have several features that suggest direct involvement in RA pathogenesis (Figure 56-3):

1. The targets of these antibodies (i.e., citrullinated proteins) are abnormally expressed and highly enriched in synovial tissue and fluid of patients with RA.[60,68,133]
2. The antibody response directed against these citrullinated antigens precedes RA onset[17,104,110,206] and is highly specific for RA and predictive of disease progression.[83-87,207]
3. ACPA positivity is closely linked with the best-known predisposing genetic risk factors for the development of RA: the HLA-DR SE alleles,[116,120,208,209] in particular, HLA-DRB1*04,[118,210,211] linking genetic predisposition and autoantibody production.
4. Peptidylcitrulline contained in peptides derived from aggrecan and vimentin is preferred to arginine in the electropositive P4 pocket of the RA-susceptible HLA-DRB1*04:01/04, and HLA-II tetramers containing these peptides identified circulating citrullinated epitope–specific $CD4^+$ T cells.[212]
5. Plasma cells producing antibodies against citrullinated proteins are present in RA synovial tissue.[46]
6. About one-half of the anti-$CCP^+$ RA patients have circulating immune complexes containing citrullinated fibrinogen, and immunohistochemical staining has shown co-localization of the fibrinogen, immunoglobulin, and complement component C3 in RA pannus tissue.[213]
7. Immune complexes containing citrullinated fibrinogen can also activate monocyte-derived macrophages to produced TNF via engagement of Fcγ receptors and Toll-like receptor 4.[214,215] Similar observations implying overlapping pathogenic properties are likely also operative in the case of RFs in RA. Recent evidence also indicates the that distinct glycosylation patterns in ACPAs may influence pathogenicity of these antibodies.[216,217]

## Potential Environmental Factors in Rheumatoid Arthritis Pathogenesis

Although abundant citrullination is found in RA synovial tissue once disease is established, no studies have addressed whether abnormal synovial citrullination precedes the onset of clinical RA (a requisite to explain the presence of antibodies against citrullinated proteins long before clinical disease). Such evidence will be very challenging to obtain. At this stage, it is therefore important to be aware that the joint is not the only possible site of abnormal citrullination that might initiate the RA-specific immune responses to citrullinated autoantigens. It is possible that the joint becomes targeted secondarily after the ACPA immune response has been initiated at another site, as a consequence of an inflammatory event triggered by a common environmental exposure, such as periodontal infection/inflammation and/or smoking (Figure 56-4). Although no evidence exists that viral proteins are citrullinated in vivo, a subset of $ACPA^+$ RA sera has been demonstrated to cross-react with in vitro citrullinated peptides from Epstein-Barr virus EBNA-1 and human papilloma virus (HPV)-47 $E2_{345–362}$ proteins.[218,219] Defining the kinetics of appearance of these antibodies during disease development, and demonstrating directly that these modified proteins are generated during natural infection, will be important to determine if this cross-reactivity is relevant to RA pathogenesis.

Tantalizing similarities and epidemiologic associations exist between periodontitis and RA, including the presence of bone erosions, association with similar class II MHC alleles and smoking, and enrichment of severe periodontal disease in patients with RA.[220-224] These connections have focused attention on the study of oral pathogens that express enzymes with PAD activity, specifically *Porphyromonas gingivalis*,[225] a Gram-negative bacterium commonly present as a biofilm in the gingival crevice and intra-cellularly in oral epithelial cells. *P. gingivalis* expresses its own citrullinating enzyme named PPAD, which produces ammonia that likely has negative effects on neutrophil function.[226] PPAD is not an ortholog of mammalian PADs, having no sequence homology with mammalian PADs, and showing significant differences in citrullination activity: (1) PPAD can citrullinate free L-arginine in addition to protein-bound arginine, (2) the enzyme does not require calcium or any other metal ion for activity, and (3) it has preference for citrullination of carboxy-terminal arginines. *P. gingivalis* also produces arginine gingipains, endopeptidases that cleave substrates after arginine residues, a process that generates C-terminal arginine residues in substrates, which are then citrullinated by PPAD.[226] Two mechanisms have been proposed by which PPAD may be relevant to RA pathogenesis: (1) by generating citrullinated bacterial and host proteins and (2) through autocitrullination. The initial finding that antibodies to CEP-1 (the immunodominant peptide from citrullinated human α-enolase) cross-react with *P. gingivalis* enolase after citrullination with rabbit PAD opened the possibility that ACPA development might be initially driven by citrullinated bacterial products, which subsequently cross-react with citrullinated endogenous proteins

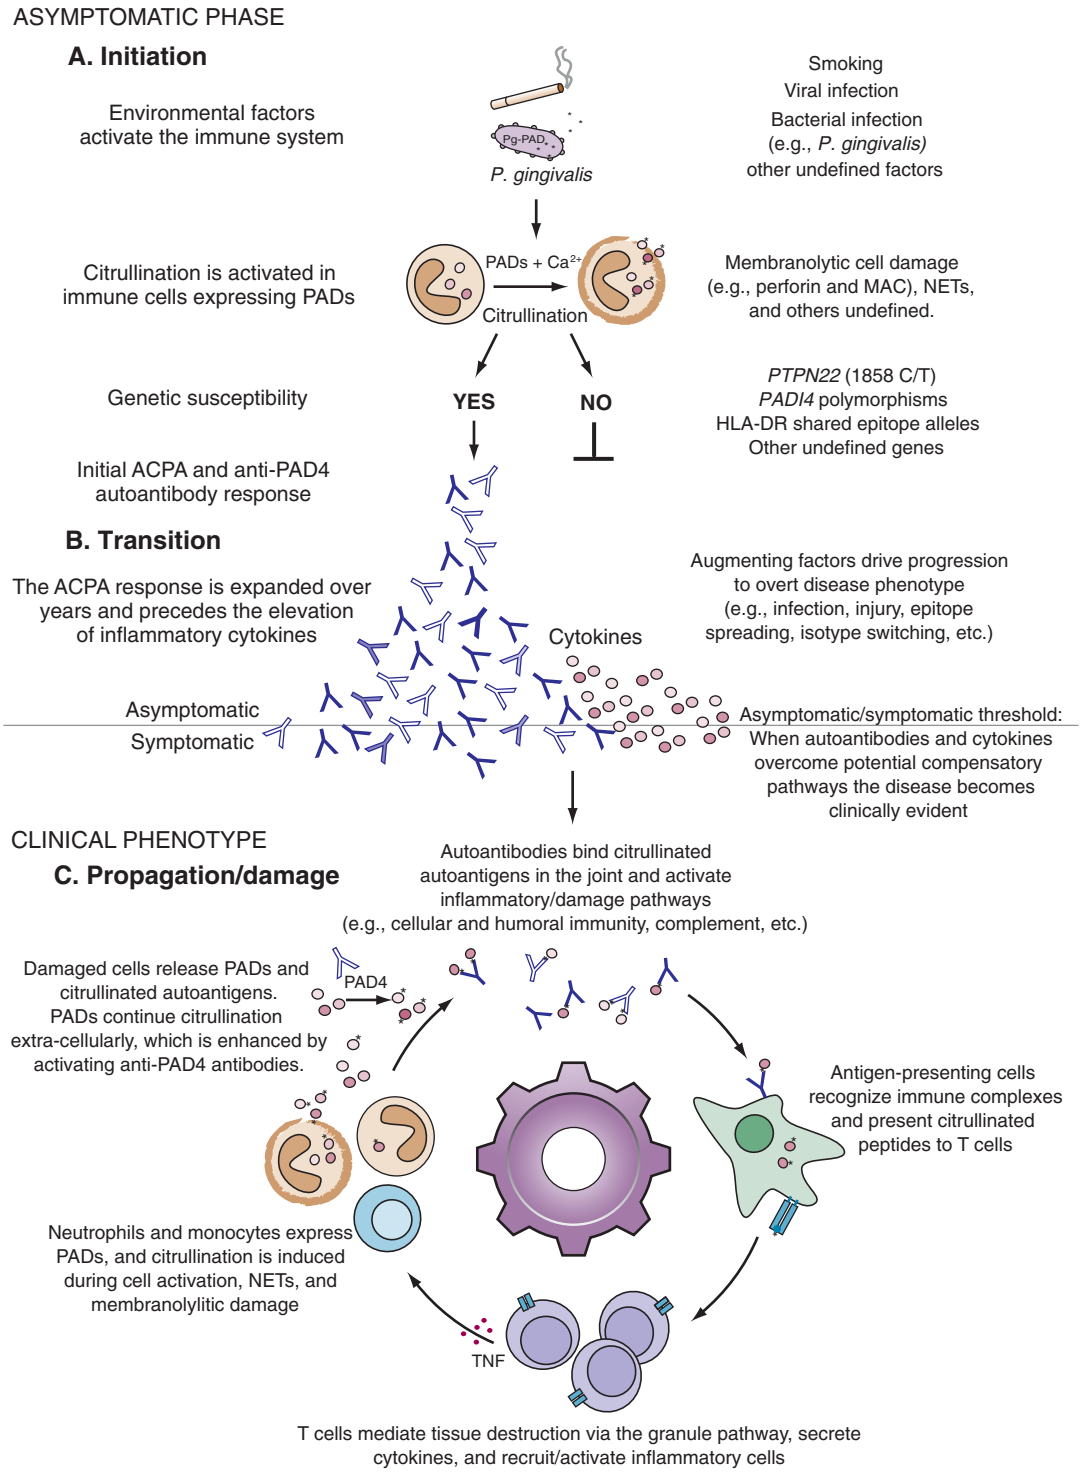

**Figure 56-4** A feed-forward model of rheumatoid arthritis (RA) pathogenesis: a pivotal role for protein citrullination. **A,** During disease initiation, immune pathways activated against environmental factors (e.g., perforin-induced cytotoxicity, neutrophil extra-cellular traps (NETs), and complement activation) generate the production of citrullinated proteins in peptidylarginine deiminase (PAD)-expressing cells. Although this process is likely normal and self-limited in the majority of the cases, some genetically susceptible persons may have the risk of developing autoantibodies against components involved in the process of citrullination (e.g., PAD4 and citrullinated proteins). This phase is likely asymptomatic because the autoantibodies are in low titer, they may not be pathogenic, and they target a limited number of citrullinated antigens.[78,217] The presence of autoantibodies may persist for several months to decades, during which a transition phase may occur. In some cases, autoantibody positivity may never progress to RA (i.e., anti-citrullinated protein antibody [ACPA]$^{+}$, RA$^{-}$ persons).[99,100] **B,** Depending on the exposure to augmenting factors that promote citrullination (e.g., infections, smoking, and injury), a transition phase occurs in which the ACPA response is amplified. This phase is characterized by an accumulation of multiple ACPA specificities, reflecting the process of epitope spreading.[78] The expansion of the autoantibody response closely correlates with the appearance of pre-clinical inflammation that includes the elevation of inflammatory cytokines, such as tumor necrosis factor (TNF), interleukin (IL)-6, IL-12p70, and interferon γ.[78] Moreover, ACPAs acquire a pro-inflammatory Fc glycosylation phenotype prior to the onset of RA.[217] Together, the changes in the autoantibody response and the elevation in cytokines predict the imminent onset of clinical RA.[78,217] It is likely that compensatory pathways might be able to sustain a "healthy state" during the process of transition. However, when autoantibodies and cytokines overcome the threshold of compensation, the clinical phase is likely initiated. **C,** Once initiated, the immune response drives a feed-forward loop of target tissue destruction and disease propagation, resulting in the clinical phenotype. Although the citrullinating events that initiate the ACPA response may occur outside the joint, during disease propagation, citrullinated autoantigens are generated in the synovium by inflammatory cell PADs, leading to amplification of the immune response within the target tissue. Citrullinated antigens are indicated (*). HLA-DR, Human leukocyte antigen–DR region; MAC, membrane attack complex.

in the microenvironment of the inflamed joint.[227] Subsequently, it was found that arginine gingipain and PPAD, respectively, cleave and citrullinate human fibrinogen and α-enolase in vitro, extending this hypothesis that host proteins citrullinated by the bacterial enzyme may also play a role in initiating the ACPA response in RA.[228] Although this model is intriguing, the citrullination of bacterial enolase by PPAD or by a human host PAD during bacterial lysis of phagocytic cells has not been demonstrated. In addition, it is unclear whether the C-terminal citrullinated human fibrinogen and α-enolase fragments generated by gingipains and PPAD are indeed recognized by ACPAs in RA. An alternative mechanism that has been proposed for the involvement of PPAD in RA pathogenesis is that autocitrullinated PPAD may act as the inciting citrullinated antigen that may trigger the ACPA response in RA.[229] Although this theory is provocative, it remains controversial because PPAD autocitrullination appears to be an artifact generated when the protein is artificially expressed in *Escherichia coli*.[230,231]

Another environmental factor with potential relevance in initiating production of ACPAs is cigarette smoking. Interestingly, recent evidence has demonstrated (at least in some populations) a strong interaction between smoking and SE alleles in the development of ACPA$^+$ RA.[119,232-234] However, whereas primarily HLA-DRB1*04 alleles have been associated with ACPA production,[118,210,211] in smokers, HLA-DRB1*0101, *0102, and *1001 alleles showed the closest association with positive anti-CCP.[119] The observation that cigarette smoking induces increased expression of PAD2 and protein citrullination in lungs,[51] that anti-CCP antibodies of the IgA class are found in about one-third of patients with recent-onset RA,[235] and that anti-CCP antibodies can be found in patients with ILD who do not have RA[99,100] has suggested that the lung or other mucosal surfaces may play a role in generating or sustaining autoantibodies to citrullinated proteins. These gene-environment interactions, playing out in microenvironments outside the joint, add important dimensions to the framework within which RA pathogenesis must be investigated and understood. Although it is possible that none of the detailed mechanisms currently defined represent the unifying mechanism of pathogenesis in RA, the broader view of potential immunizing environments and the search for a frequent worldwide environmental exposure is of great importance.

CHAPTER 57

# Acute Phase Reactants and the Concept of Inflammation

César E. Fors Nieves • Bruce N. Cronstein • Amit Saxena

**KEY POINTS**

- Inflammation comprises a complex and highly variable set of processes that represent a response to tissue damage from infection or injury.
- The acute phase response, a major accompaniment of inflammation, is induced by inflammation-associated cytokines and includes a reorchestration of acute phase protein synthesis by the liver.
- The erythrocyte sedimentation rate (ESR), the most commonly used clinical measure of inflammation, depends on numerous physical and chemical characteristics of blood, many of which are not related to inflammation.
- The quintessential acute phase protein, C-reactive protein (CRP), not only offers biomarker utility in the clinic, but also plays a role in host defense by recognition of biologic substrates, activation of the complement pathway, and by binding to leukocytes.
- Cytokines, chemokines, adhesion molecules, and other products of activated inflammatory cells are secreted during inflammation and play roles in the inflammatory response, but several problems limit the clinical usefulness of their quantitation for routine clinical purposes.
- CRP and ESR may reflect disease activity and correlate with disease prognosis in rheumatoid arthritis but generally are not helpful for differential diagnosis.
- Although CRP and ESR correlate with clinical activity in many inflammatory rheumatic diseases, the absent or modest CRP response seen in some patients with active systemic lupus erythematosus remains unexplained.
- CRP or ESR is elevated in more than 80% of patients with polymyalgia rheumatica and in approximately 95% of patients with giant cell arteritis. Both are useful for disease follow-up, but their imperfect correlation with disease activity indicates that these measures cannot supplant sound clinical judgment.
- Minor elevations of CRP, within the normal population reference range, are associated with increased risk of myocardial infarction but are nonspecific (especially in patients with rheumatic disease). Minor CRP elevation is associated with well-recognized risk factors for cardiovascular disease, which may explain its predictive value.

The inflammatory response is the body's natural defense against unchecked tissue damage from infection or injury. It occurs during the acute phase of an inciting event and, if the stimulus is not eliminated, in a chronic, putatively healing stage. When excessive or uncontrolled, these responses have the potential to cause significant harm to the host through processes such as autoimmune diseases, allergic reactions, and septic shock.

The concept of inflammation itself has evolved over thousands of years. Celsus first described the cardinal signs of redness, swelling, heat, and pain in the first century AD. The fifth sign, loss of function, is often attributed to Galen's work in second century.[1] Since that time, countless advances have been made in the understanding of inflammation, from histologic findings of inflammatory cells within tissues, to the discovery of hematologic and soluble mediators such as cytokines and complement. Also, the molecular signaling pathways that drive both its protective effects and the inappropriate injurious responses have been recently elucidated.

With increasing insight into mechanisms of the inflammatory response has come an appreciation of its significant complexity. Molecular and microscopic processes are different during acute and chronic stages, and diverse responses are induced by various types of exogenous and endogenous stimuli (e.g., bacteria, viruses, parasites, crystals, allergens, and ischemia). More recently, the role of the milieu of the inflammatory response, especially at the level of the vascular endothelium, has taken on considerable importance.[2] Furthermore, inherent redundancies of functions have been noted, as have interactions between the mediators of inflammation that allow for a broad, effective response, but these redundancies make it difficult to understand the pathways of inflammation in a linear fashion. These intricacies have resulted in a vague definition and on continued reliance on the final downstream macroscopic cardinal signs to tie together all of the ongoing processes. It is these same intricacies that have made evaluation of inflammation through laboratory tests imprecise.

Basic hematologic abnormalities may give clues to the presence of inflammation, but different patterns are often associated with underlying causes and are not universally found. Leukocytosis can be seen in infections, acute crystal diseases, and some autoimmune disorders such as adult Still's disease. Anemia is often associated with certain diseases that cause chronic inflammation, such as rheumatoid arthritis (RA). Reactive thrombocytosis occurs secondary to the release of cytokines after an inciting infectious or inflammatory event, and the role of platelets and platelet-derived mediators in stimulating inflammation has been described at the molecular level.[3]

Laboratory tests most commonly used by physicians to obtain information about the extent of inflammation are those that measure the acute phase reaction. In response to injury, local inflammatory cells secrete cytokines that

influence the liver to increase or decrease production of various proteins. The erythrocyte sedimentation rate (ESR) has been the classic marker of inflammation, with serum C-reactive protein (CRP) taking on an increasingly prominent role. Other novel inflammatory markers such as procalcitonin have been recognized, but their clinical utility has yet to be fully determined.

CRP elevations, especially minor ones, have been noted in numerous conditions that traditionally have not been considered inflammatory, most significantly involving the cardiovascular system. This has shed light on subclinical inflammation as a possible factor in the pathogenesis of a great number of diseases.

## ACUTE PHASE RESPONSE

Within minutes of tissue injury, activation of the innate immune system induces cytokine production that results in a multisystem acute phase response involving the liver, vascular system, bone marrow, and central nervous system.[4,5] Many elements of the reaction can be regarded as part of the innate response and are defensive or adaptive in nature.[6] Mouse studies have shown that as much as 7% of the regulatory gene pool undergoes significant changes in expression during inflammation, and that induction of liver acute phase genes is mediated by the transcription factor signal transducer and activator of transcription 3 (STAT3).[7-9]

Although the acute phase response can trigger numerous neuroendocrine, hematopoietic, and metabolic effects, the changes in plasma proteins synthesized by hepatocytes are monitored as signs of underlying inflammation (Tables 57-1 and 57-2). An acute phase protein is one in which the plasma concentration changes from baseline by at least 25% during inflammation; responses vary in terms of concentration and kinetics (Figure 57-1).[10] CRP and serum amyloid A (SAA) levels increase more than 1000-fold during acute infection and peak at 2 to 3 days. Concentrations of other proteins peak at longer periods and can range from a 50% increase in complement and ceruloplasmin, to a several-fold amplification in haptoglobin, fibrinogen, α1-proteinase inhibitor, and α1-acid glycoprotein. Other proteins are negative acute phase proteins, the concentrations of which fall during the inflammatory response. These include antithrombin III, protein S, prealbumin, albumin, transferrin, and apolipoprotein A-I.[4,5]

Hepatic stimulation of acute phase proteins is induced by cytokines released by activated monocytes, macrophages, neutrophils, natural killer (NK) cells, and endothelial cells acting at the front lines of the inflammatory response. The main cytokine influencing the liver is IL-6, once called the "hepatocyte-stimulating factor." It likely mediates protein expression via the Janus kinase (JAK) and STAT3 pathways, as well as C/EBP family members and Rel proteins (nuclear factor-κB [NF-κB]).[9,11] During initial stages, IL-1 and TNF synergize with IL-6 and trigger further IL-6 production, but their roles are limited.[12] The soluble IL-6 receptor amplifies IL-6 effects both locally and systemically. IL-6 also performs a protective role during disease, inducing the expression of an IL-1 receptor antagonist.[13]

Acute phase protein levels are not uniform in their expression; this is likely related to the underlying pathophysiologic state and is regulated by different combinations and interactions of cytokines.[5] The roles of the acute phase proteins themselves will be discussed throughout the chapter but have been found to include direct involvement in host defense by activation of the complement, proteinase inhibition, and antioxidant activity.[14] However, some of the described in vitro effects of proteins may not be relevant in vivo.

| Increased plasma retinol and glutathione concentrations |

From Gabay C, Kushner I: Acute-phase proteins and other systemic responses to inflammation. *N Engl J Med* 340:448–454, 1999.

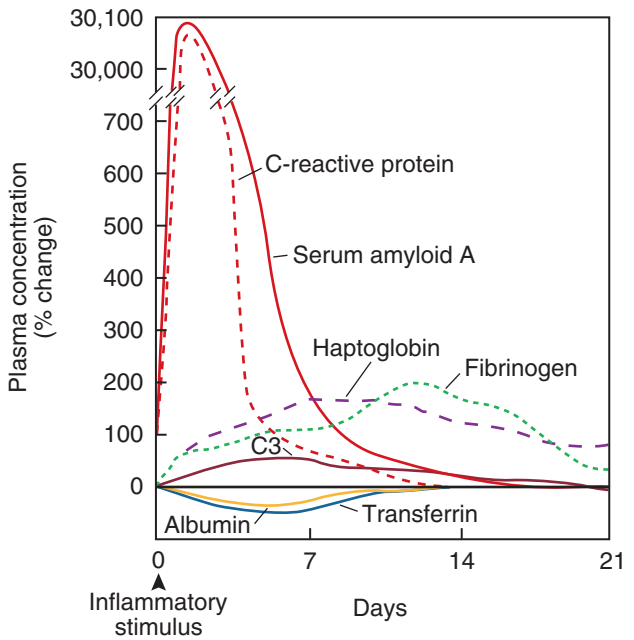

**Figure 57-1** Typical plasma acute phase protein changes after a moderate inflammatory stimulus. Several patterns of response are seen: major acute phase protein, increase 100-fold (e.g., C-reactive protein, serum amyloid A); moderate acute phase protein, increase twofold to fourfold (e.g., fibrinogen and haptoglobin); minor acute phase protein, increase 50% to 100% (e.g., complement C3); and negative acute phase protein, decrease (e.g., albumin, transferrin). *(Modified from Gitlin JD, Colten HR: Molecular biology of the acute-phase plasma proteins. In Pick E, Landy M, editors:* Lymphokines*, vol 14, San Diego, 1987, Academic Press, pp 123–153.)*

tube and the rate of fall of erythrocytes is measured. The ancient Greeks recognized increased red blood cell (RBC) sedimentation as a way to detect "bad bodily humors," but our modern understanding and use of RBC sedimentation as a test date back to the German scholar Fahraeus in 1918.[15] He determined that certain plasma proteins, especially fibrinogen, are able to lower the electrostatic charge on RBC surfaces so they can aggregate, form rouleaux, and fall faster.

Several factors are involved in acceleration of ESR. Asymmetric plasma proteins, such as fibrinogen and, to a lesser extent, alpha$_2$, beta, and gamma globulins decrease the negative charge of erythrocytes (zeta potential) that prevents rouleaux formation. Red cell factors also play a role in that changes in plasma ratios in anemic states also favor rouleaux. However, microcytosis, polycythemia, and abnormally shaped RBCs (e.g., sickle cells and spherocytes) hinder aggregation and lower the ESR.[16] Conditions that elevate fibrinogen, even if they are not necessarily considered inflammatory, can raise ESR. These include pregnancy, diabetes, end-stage renal disease, and heart disease. Major increases in the concentration of a single molecular species, such as a monoclonal immunoglobulin in multiple myeloma, also cause increased sedimentation.[17] The ESR is elevated in obesity, as is CRP, presumably as a result of IL-6 secretion by adipocytes.[18] Factors such as glucocorticoids, cryoglobulins, hypofibrinogenemia, and hyperviscosity lower the value.[4] The physiochemical dynamics that allow for sedimentation has been a continued source of debate, with disparate models presented to explain how proteins on cell surfaces interact to cause RBC aggregation.[19]

Although novel and rapid tests for ESR have proven promising, the International Committee for Standardization in Hematology continues to recommend the Westergren technique of testing anti-coagulated blood.[20,21] The usual accepted upper limits of normal are 15 mm/hr for males and 20 mm/hr for females; however, the ESR increases with age and varies by race, which calls the reliability of the test into question. A simple formula for calculating the upper limit of normal ESR at any age has been used regularly. In men, age in years divided by 2; in women, 10 plus age in years divided by 2. Despite the ability to control for age, other limitations of the test have been noted and are listed in Table 57-3. The relative virtues of CRP determination have diminished some of the importance of ESR, but it remains an easy, inexpensive test with a wealth of background literature. Therefore the sedimentation rate continues to play a prominent role in clinical practice.

## C-Reactive Protein

C-reactive protein is an acute phase protein, the serum concentration of which reflects ongoing inflammation better than other tests in most, but not all, diseases.[22] CRP was identified in 1930, when sera obtained from patients with *Streptococcus* pneumonia infection were found to contain a protein that could bind to the "C" polysaccharide of the bacterial cell wall. This protein circulates as a 115 kDa pentamer of noncovalently linked 23 kDa subunits, which has been highly conserved during hundreds of millions of years of evolution. In contrast to immunoglobulins and complement components, CRP deficiency in humans has

**TABLE 57-3** Comparison of Erythrocyte Sedimentation Rate and C-Reactive Protein

| | Erythrocyte Sedimentation Rate | C-Reactive Protein |
|---|---|---|
| Advantages | Much clinical information in the literature<br>May reflect overall health status | Rapid response to inflammatory stimuli<br>Wide range of clinically relevant values are detectable<br>Unaffected by age and gender<br>Reflects value of a single acute phase protein<br>Can be measured on stored sera<br>Quantitation is precise and reproducible |
| Disadvantages | Affected by red blood cell morphology<br>Affected by anemia and polycythemia<br>Reflects levels of many plasma proteins, not all of which are acute phase proteins<br>Responds slowly to inflammatory stimuli<br>Requires fresh sample<br>May be affected by drugs | Not sensitive to changes in SLE disease activity |

not been described. Genome-wide associated studies performed recently have shown that at least seven distinct loci are involved in the basal expression of CRP,[23-25] which is upregulated upon stimulation by the transcription factors C/EBP and Rel.[26] It is present in trace concentrations in the plasma of all humans (roughly 1 mg/L, with higher concentrations in women and the elderly). Plasma C-reactive protein is synthesized by hepatocytes, although other sites of local production and possibly minimal secretion have been suggested.

The precise function of CRP is unknown and may be varied, but it exhibits important recognition and activation capabilities, and it binds to numerous ligands.[27] CRP recognizes phosphocholine, phospholipids, fibronectin, chromatin, and histones, all of which are exposed at sites of tissue damage and by apoptotic cells; CRP may target them for clearance.[28] C-reactive protein bridges the gap between innate and adaptive immunity by activating the classic complement pathway and interacting with cells of the immune system through binding of Fcγ receptors.[29,30] CRP induces inflammatory cytokines, tissue factors, and shedding of the IL-6 receptor, all of which result in a complement-dependent increase in tissue damage.[28] Other CRP functions are anti-inflammatory, including promotion of the non-inflammatory clearance of apoptotic cells and prevention of neutrophil adhesion to the endothelium.[31,32] Thus CRP may play many pathophysiologic roles during the course of the inflammatory process.[14,33]

After an acute inflammatory stimulus, CRP concentration increases rapidly and peaks at 2 to 3 days at levels that reflect the extent of tissue injury. If the stimulus has been removed, serum CRP levels drop rapidly, with a half-life of roughly 19 hours.[34] Persistent elevations in CRP are seen in chronic inflammatory states such as active RA, pulmonary tuberculosis, or extensive malignant disease.

Immunoassays and laser nephelometry are used at modest cost to quantify serum CRP levels. Most healthy adults have levels less than 0.3 mg/dL. The significance of minor elevations in CRP is a subject of debate and will be discussed subsequently. However, usual methods of CRP determination are less precise at concentrations in the range of 0.3 to 1 mg/dL, so high-sensitivity (hs) CRP methods are used to accurately measure these levels. Generally, concentrations greater than 1 mg/dL reflect clinically significant inflammatory disease.[35,36] Concentrations of 1 to 10 mg/dL can be considered to represent moderate increases, and concentrations greater than 10 mg/dL show marked increases. Most patients with extremely high levels (e.g., >15 mg/dL) have bacterial infection. One study found that in patients with CRP concentrations greater than 50 mg/dL, infection was present in 88% of participants.[37] Clinical conditions associated with varying degrees of elevation of CRP are listed in Table 57-4, and the range of CRP concentrations in many rheumatologic diseases is shown in Figure 57-2.

**TABLE 57-4** Conditions Associated with Elevated C-Reactive Protein Levels

| |

| Most systemic autoimmune diseases |
| Rheumatoid arthritis |
| **Marked Elevation (>10 mg/dL)** |
| Acute bacterial infection (80% to 85%) |
| Major trauma |
| Systemic vasculitis |

Several limitations associated with the use of C-reactive protein measurement must be acknowledged. No uniformity in reporting concentrations has been noted between laboratories, and values can be conveyed in mg/L, μg/mL, or mg/dL. Similar to ESR, population studies show a skewed, rather than gaussian, distribution, which renders parametric statistical tests inappropriate for interpretation of CRP data. Population differences in CRP levels in the United States have been reported between sexes and among racial groups. This is presumably also prevalent as an issue in practice in other populations globally. Elevation of C-reactive protein in the elderly may represent age-related disorders, the pathogenesis of which may involve low-grade inflammation, which complicates the issue of what levels are considered normal.[38]

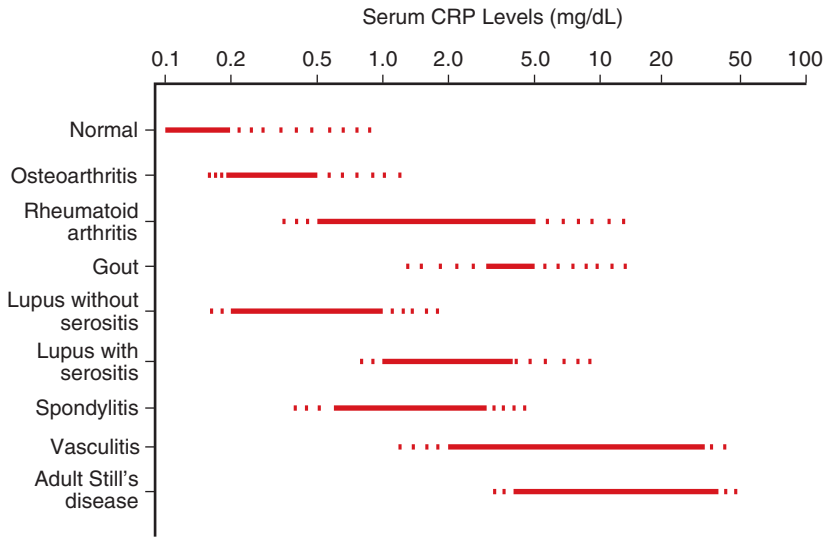

**Figure 57-2** Range of C-reactive protein (CRP) levels in rheumatic disease. Authors' estimates of expected levels of CRP (mg/dL) in certain rheumatic diseases.

## Procalcitonin

Procalcitonin (PCT), a propeptide of calcitonin, has recently received increased attention as a useful measure to differentiate between acute bacterial infection and other inflammatory and febrile syndromes. Studies have shown that elevated serum levels of PCT have a significantly higher specificity for infection than ESR and CRP.[39-42] PCT has been studied extensively as a clinical tool to facilitate the decision as to when to start and stop anti-bacterial agents in patients with pneumonia,[43,44] and it has also shown promise in differentiating between infectious and noninfectious causes of fever after orthopedic surgery, in which ESR and CRP levels can be difficult to interpret.[45,46] For all of these reasons, it remains an intriguing clinical tool for use in patients with fevers in the setting of autoimmune disease who are commonly on immunosuppressive medications and at higher risk of infection.

Normally produced in the C-cells of the thyroid gland, PCT is usually cleaved into calcitonin, katacalcin, and an N-terminal residue. Under normal circumstances, PCT is not released into the bloodstream; however, during severe infection plasma, levels can increase dramatically.[47,48] Interestingly, this does not lead to an increase in plasma calcitonin levels or activity. At this time, the exact site of PCT production, as well as its pathophysiologic role during sepsis, remains uncertain.[49]

In healthy humans, PCT levels are undetectable or very low (<0.1 ng/mL). During systemic bacterial infection, PCT levels can increase to higher than 100 ng/mL. Currently available diagnostic tests measure the calcitonin/N-ProCT part of the protein and therefore only a fragment of the 114 to 116 amino-acid chain of the prohormone. A useful reference range to exclude sepsis and systemic inflammation is less than or equal to 0.2 ng/mL. Plasma levels of greater than or equal to 0.5 ng/mL should be interpreted as abnormal and suggest sepsis. After reaching peak levels, circulating PCT has a half-life of approximately 22 to 35 hours in serum, and its concentration declines with a 50% plasma-disappearance rate of roughly 1 to 1½ days. It is worth noting that in patients with severe renal dysfunction these rates may be prolonged, but accumulation does not occur.[50]

As a biomarker for infection in autoimmune diseases, the role of PCT has not yet been fully established. In contrast to CRP, PCT levels are not elevated in in the majority of cases of noninfectious inflammation or nonbacterial infection. However, exceptions to this rule include some vasculitis syndromes such as Kawasaki's disease, Goodpasture's syndrome, adult-onset Still's disease[51,52] and granulomatosis with polyangiitis,[53] for which observational studies have demonstrated elevated levels of PCT in patients without evidence of bacterial infection. In systemic lupus erythematosus, data are mixed, and no definitive statement regarding the usefulness of PCT can be made at this time.[54-56]

## Other Acute Phase Proteins

Measurement of other acute phase proteins has been of limited value clinically because their responses to tissue injury are often slower, and the magnitude of concentration change is smaller than with CRP. Serum amyloid A (SAA), a circulating family of proteins produced by hepatocytes, adipocytes, macrophages, and fibroblast-like synoviocytes has been correlated with disease activity in a number of inflammatory disorders.[57] However, reliable testing for acute phase SAA is not widely available, and data about levels expected in disease are limited. Serum ferritin is moderately increased, triggered by cytokines such as IL-1, IL-6, IL-18, and TNF. Levels are frequently high in adult-onset Still's disease and systemic lupus erythematosus (SLE), and they correlate with disease activity.[58,59] Hepcidin, a liver-derived anti-microbial peptide and regulator of iron homeostasis, is induced by inflammation, and by IL-6 in particular.[60] Its levels rise in parallel with ferritin, and it is important in the development of anemia of chronic disease, acting as a negative regulator of iron absorption and macrophage iron release teleologically, to deprive microbes of iron.[61] Transferrin, which binds and transports iron, is a negative acute phase protein.

Apolipoprotein A-I, the principal protein constituent of high-density lipoprotein (HDL), is another negative acute phase protein. In chronic inflammatory diseases such as RA and SLE, decreased levels may contribute to increased risk of thrombotic events.[62,63] Serum albumin and prealbumin (transthyretin) are also negative acute phase proteins, although their measurement is not more helpful in diagnosis or prognosis than standard tests.[64] Serum complement fractions become depressed when the system is activated in certain autoimmune disorders but otherwise rise during the acute phase response.

## Cytokines

Although not acute phase proteins in the classic sense, cytokines display the most striking acute phase behavior of any circulating proteins. IL-6 responds dramatically to tissue injury, with concentration changes that are faster and greater than those of CRP or SAA. Acute inflammation and chronic inflammation have been associated with increases in IL-6, and serum levels of this cytokine have been correlated with the severity and course of disease in RA, juvenile arthritis, ankylosing spondylitis, and polymyalgia rheumatica (PMR).[65,66] It is also more sensitive than ESR for detecting disease activity in giant cell arteritis (GCA).[67] IL-6 levels may be useful in monitoring inflammation if hepatocytes are damaged to the point that they are not able to synthesize acute phase proteins.[4] Knowledge of soluble IL-6 receptor levels may also be helpful in this regard. The importance of cytokines such as TNF and IL-1 has been inferred by the successful reduction of inflammation by their therapeutic inhibitors. Certain diseases, such as the TNF receptor–associated periodic syndrome (TRAPS) and the autoinflammatory syndromes that involve mutations of the inflammasome controlling IL-1, point to the importance of these cytokines.

Increased levels of several other cytokines and circulating cytokine receptors have been associated with inflammation or disease activity as well (Table 57-5).[67,68] Different patterns of cytokine responses have been reported in different diseases, suggesting that cytokine determinations are potentially useful clinically.[69,70] However, their quantitation presents several problems related to their short plasma half-lives, the presence of blocking factors and natural inhibitors, and other technical considerations.[71] At present, high costs, limited availability, and the absence of standardization discourage the measurement of plasma cytokines and their receptors in clinical practice.

# ACUTE PHASE REACTANTS IN THE MANAGEMENT OF RHEUMATIC DISEASES

Measurement of ESR and CRP has no role in the diagnosis of any particular disease, including RA, osteoarthritis, SLE, PMR, GCA, or other inflammatory arthropathies. However, these measurements can be clinically helpful in three ways: (1) in evaluating the extent or severity of inflammation, (2) in monitoring changes in disease activity over time, and (3) in assessing prognosis.

## Rheumatoid Arthritis

ESR and CRP cannot be used in the diagnosis of RA, because 45% of patients may have normal serum levels at presentation,[72] although these values represent part of the diagnostic syndrome or classification criteria sets. These tests are more appropriately applied in RA for monitoring disease activity and response to therapy. Although ESR traditionally has been more widely used for these purposes, many studies have suggested that CRP levels correlate better with disease activity.[73] Some recent reports state that CRP levels may overestimate disease response compared with ESR; others claim that differences between the two are minimal.[73-75] The existence of patients with depressed CRP concentrations caused by carrying low-CRP–associated genetic variants must be taken into account when this test is used universally.[76] Matrix metalloproteinase (MMP)-3, pro-MMP-3, and soluble E-selectin have also been proposed as markers for RA disease activity. Their measurements correlate with CRP levels but do not provide more information than is provided by standard tests.[77-79]

CRP levels average 2 to 3 mg/dL in adult patients with RA who have moderate disease activity.[80] However, variation is considerable. At least 5% to 10% of patients have values in the normal range, whereas a few patients with severe disease activity have levels greater than 10 mg/dL. ESR values have been found to remain stable over the years.[81] ESR and CRP have long been used to follow the response to therapy; in general, effective disease-modifying anti-rheumatic drug therapy decreases CRP levels by approximately 40%. Inhibition of joint damage by these agents usually is accompanied by marked improvement in acute phase reactants. Progression of joint damage can occur while the patient is on therapy, however, despite decreases in ESR and CRP.[82] Even more striking improvement has been seen with biologic agents introduced since the 1990s, providing objective laboratory support for the encouraging clinical responses observed. In early reports of anti-TNF therapy, CRP and SAA levels declined by 75% and 85%, respectively, in approximately 1 week.[83] Treatment with abatacept, the T cell CD80/CD86:CD28 co-stimulation modulator, resulted in significant decreases in CRP at both 90 and 360 days of therapy.[84] Tofacitinib, a JAK inhibitor, also appeared to effectively decrease DAS28-ESR scores in RA patients in clinical trials; therefore it may

be a useful tool to monitor disease activity.[85] In one study, failure to suppress CRP levels 2 weeks after initiation of infliximab therapy identified most patients who would prove to be clinical nonresponders after 12 weeks.[86] In contrast to traditional disease-modifying anti-rheumatic drugs, TNF inhibitors have been found to inhibit joint damage even while clinical activity, reflected by CRP levels, remains high.[87] Tocilizumab, a human IL-6 receptor antibody, improves RA by inhibiting effects of the cytokine. However, because of its mechanism of action, inflammatory markers such as ESR and CRP drop to negative values, so that tracking them may not reflect the actual effect of the drug; care must be taken when monitoring disease activity during tocilizumab therapy.[88,89]

ESR and CRP also have value as prognostic indicators in RA. Elevated acute phase reactant levels are associated with early synovitis and erosions as detected by magnetic resonance imaging, with inflammatory cellular infiltrates in synovium, and with osteoclastic activation and reduced bone mineral density.[90-92] CRP predicts radiographic progression, as do ESR and the matrix metalloproteinases MMP-3 and MMP-1.[77,78,93-95] Finally, and perhaps most important, acute phase reactants correlate with work disability on long-term follow-up and predict progression to major joint replacement.[96,97] As in the normal population, CRP levels are associated with death from cardiovascular disease.[98] In patients with RA in whom heart failure developed, ESR was higher during the 6-month period immediately preceding the onset of heart failure than earlier in tits course.[99]

Serum or synovial fluid levels of many other tissue products (see Table 57-5) have been correlated with clinical measures of disease activity, severity, and radiographic damage.

Newer quantitative and objective assays that incorporate some of the measures previously mentioned as well as other novel ones, have recently come into the market to aid in the management and earlier diagnosis of patients with RA. Multibiomarker disease activity (MBDA) tests are increasingly popular and could play a significant role the future management and study of RA; however, more studies are required to determine their clinical usefulness across different mechanistic interventions.

## Systemic Lupus Erythematosus

Although serum levels of CRP often parallel disease activity in autoimmune disorders, it has been recognized that SLE is an exception.[100] Although marked CRP responses are seen in subsets of patients, such as those with serositis or chronic synovitis, many (e.g., patients with nephritis) show mild or no elevation during periods of activity.[101-103] Serum levels of SAA are also relatively low in comparison with those of patients with RA, which may explain why rates of secondary amyloidosis are decreased in these patients[104] In contrast, ESR correlates with disease activity and accrued tissue damage in SLE.[105] Fibrinogen levels increased over time in patients, regardless of disease activity.[106] Data are insufficient to evaluate the potential use of some of the other newer markers described previously, including PCT, but many SLE patients with normal CRP levels show elevated IL-6 concentrations.[107] Therefore a deficiency in IL-6 does not explain the muted CRP response in SLE.

Although the concomitant decrease in SAA may point against it, several investigations have raised the possibility that low CRP levels may be related to the pathogenesis of SLE: (1) An association has been noted between SLE and a genetic polymorphism associated with low CRP levels; (2) it has been observed that low CRP levels may contribute to defective clearance of autoantigens during apoptosis; and (3) the therapeutic efficacy of CRP has been reported in mouse models of SLE.[101,108-111] Recent studies have also raised the possibility that type I interferon (IFN), which is expressed significantly in SLE, may inhibit CRP expression.[112,113]

Substantial CRP elevation in SLE patients is more likely to result from superimposed infection than from activation of lupus. CRP levels greater than 6 mg/dL in these patients should serve as an impetus to exclude the possibility of infection, just as they should in other diseases.[10] Such levels should not be regarded as proof of infection, however; as indicated earlier, marked CRP elevation related to active SLE can be seen in the absence of infection.

Carotid plaque and intima-media wall thickness, correlates of atherosclerotic vascular disease, have been found in association with minor CRP elevation in women with SLE, as they have in patients with RA.[114,115]

## Polymyalgia Rheumatica and Giant Cell Arteritis

The diagnosis of PMR or GCA is supported by an elevated ESR, often greater than 100 mm/hr. However, such elevation is no longer regarded as a sine qua non of these disorders; continuing reports suggest that 10% to 20% of patients with PMR can have "normal" ESRs, depending on which value is taken as the limit of normal. Such patients tend to have fewer systemic symptoms and less severe, less frequent anemia.[116] They have the same frequency of positive temporal artery biopsy results, however, as patients with elevated ESR.[117,118]

Only approximately 5% of patients with GCA had ESR values less than 40 mm/hr; these patients had fewer visual and systemic symptoms than patients with high ESR values.[119] In contrast to these findings, ESR and CRP were found to be significantly lower in patients with ocular involvement, most commonly in the range of 70 mm/hr to 100 mm/hr. Patients with ESR greater than 100 mm/hr had decreased incidence of visual ischemic events.[120-122]

In PMR and GCA, CRP and ESR have been regarded in the past as equally valuable in assessing disease activity. However, recent reports suggest that CRP is more sensitive for both conditions and should be included routinely in the diagnostic workup.[118,123,124] The report that IL-6 is more sensitive than ESR for indicating disease activity in GCA is of particular interest.[125] Subsets of patients with PMR who have persistently elevated levels of CRP and IL-6 despite corticosteroid treatment have a higher risk of relapse.[126] A polymorphism at the IL-6 gene promoter has characterized these PMR patients with persistently elevated levels of the cytokine.[127] Clinical manifestations of disease, even in the presence of a normal ESR or CRP level, should not be ignored. Extreme elevation of the ESR in the absence of symptoms of PMR or GCA should raise suspicion of other disorders, such as infection, malignancy, or renal

disease. PCT levels in patients with PMR or GCA are usually normal according to a French prospective study. Elevated PCT levels in these patients with a normal temporal artery biopsy would be suggestive of an alternate diagnosis.[128]

Numerous markers of endothelial perturbation, although not acute phase reactants in the strict sense, are elevated in plasma in various inflammatory disorders of vessels, particularly PMR, GCA, and other vasculitides.[129] These molecules include von Willebrand factor, thrombomodulin, some vasoactive prostanoids, and a variety of adhesion molecules, such as vascular cell adhesion molecule-1.

### Adult-Onset Still's Disease

Markedly elevated concentrations of ferritin, disproportionately high compared with those of other acute phase reactants, have long been noted in adult-onset Still's disease but are not specific.[130] Only a small percentage, commonly less than 20%, of ferritin is glycosylated in adult-onset Still's disease, a criterion included in recently proposed classification criteria for this condition.[131,132] Extremely elevated ferritin levels have been found in macrophage activation syndrome, and 40% of individuals with this condition meet the criteria for adult-onset Still's disease, suggesting to some that the two disorders are not distinct entities.[133-135] Concentrations of serum IL-18 were extremely elevated in patients with active adult-onset Still's disease compared with those of patients with other connective tissue diseases or of healthy individuals and were correlated with serum ferritin values and disease severity.[136] The cytokine profile in the sera of patients suggests a type 1 T helper (Th) cell response, with significantly higher levels of TNF, IL-6, and IL-8, in addition to IL-18.[137] The role of IL-1 has been inferred from significant improvement in disease activity by the IL-1 receptor antagonist, anakinra.[138,139] It has been suggested that IFN-α may be responsible for the hyperferritinemia of adult-onset Still's disease.[130] CRP levels are usually markedly elevated in this disease, and PCT levels have also been found to be disproportionately elevated without evidence of acute bacterial infection in these patients.[51,52]

### Ankylosing Spondylitis

Ankylosing spondylitis ordinarily does not lead to a substantial increase in ESR or CRP. Median ESR and CRP levels are 13 mm/hr and 1.6 mg/dL, respectively, in patients with only spinal involvement, and 21 mm/hr and 2.5 mg/dL in patients with peripheral involvement or associated inflammatory bowel disease.[140] Treatment with infliximab led to an average decrease of 75% in CRP concentration after 12 weeks. Patients with lower CRP levels showed little improvement, however, raising the possibility that patients with higher CRP values show better responses to anti-TNF treatment than patients with lower CRP levels.[141-143] High-sensitivity CRP may better correlate with clinical disease activity compared with standard CRP testing.[144] It has been reported that levels of IL-8, IL-17, and IL-23 are elevated in the serum of patients with active ankylosing spondylitis, and polymorphisms in the IL-23 receptor gene are associated with the disease.[145-147]

### Osteoarthritis

Minor CRP elevations of 0.3 to 1.0 mg/dL have been reported in patients with osteoarthritis, particularly those with progressive joint damage.[148] However, no evidence supports this association independent of body mass index (BMI), because obesity is a common accompaniment of osteoarthritis.[149] Although local inflammation likely plays a role in the pathogenesis of osteoarthritis, systemic inflammation likely does not. However, CRP levels are higher in patients with erosive osteoarthritis of the hand than in those with nonerosive osteoarthritis.[150]

### Other Rheumatic Diseases

Acute phase markers are elevated in numerous rheumatic diseases while the inflammatory cascade commences. Elevated ESR and CRP can be found in systemic vasculitides, crystal arthropathies, psoriatic and reactive arthritides, and infectious joint diseases.[151-154] Monitoring for elevated SAA levels has been proposed as a tool for diagnosis and medication adjustment in familial Mediterranean fever,[155] although this test is not widely available, limiting its utility. CRP is often normal in patients with primary Sjögren's syndrome, and those with elevated responses do not differ clinically from patients with normal levels.[156] Oligoarticular-onset juvenile idiopathic arthritis is classically considered as not associated with elevated inflammatory markers, although they are present in patients most at risk for systemic disease.[157]

## PRACTICAL USE OF ACUTE PHASE REACTANTS

In the past, rheumatologists were found to use the ESR more than twice as frequently as they did CRP levels,[158] although ESR reflects many complex, poorly understood changes in the physical and chemical characteristics of blood not associated with inflammation. As indicated earlier, the reference normal values for ESR are unclear. It is well established that mean ESR values increase substantially with age and differ between men and women. Difficulties associated with interpretation of the ESR and an increasingly positive clinical experience with CRP suggest that rheumatologists may benefit from relying more on CRP than ESR testing.[159] No single ideal test can be used to evaluate the acute phase response, however. The relative virtues of these tests in following patients with RA have been discussed.[74,160]

Discrepancies between ESR and CRP may result from effects of blood constituents that are not related to inflammation, but that can influence the ESR. In addition, patterns of acute phase protein changes differ in different conditions.[5] ESR may be markedly elevated in many patients with active SLE, whereas the CRP is normal. Undoubtedly, numerous other clinical situations exist in which similar discrepancies occur. Although a falsely high ESR has many non-inflammatory physicochemical causes (some known, and many unknown), CRP values greater than 1 mg/dL almost invariably reflect a clinically significant inflammatory process. In light of these considerations, many authors believe that several tests, rather than a single test, should be performed and interpreted in their clinical context. It

has been suggested that ESR, which is associated with anemia and immunoglobulin levels, may reflect general severity in RA, whereas CRP is a better test of active inflammation per se.[161]

## C-REACTIVE PROTEIN AND HEALTH: ASSOCIATIONS WITH NONRHEUMATOLOGIC CONDITIONS

Although most ostensibly healthy individuals have CRP concentrations of 0.3 mg/dL or less, some have concentrations greater than 1 mg/dL. Such minor CRP elevation has long been attributed to trivial tissue injury or to minimal inflammatory processes, such as gingivitis. However, recent data indicate that CRP concentrations between 0.3 and 1 mg/dL have clinical relevance. This finding has led to an explosion of published literature measuring CRP levels in cardiac, neurologic, neoplastic, pulmonary, and even psychiatric disease.[162-166] The foundation of these investigations is the well-established notion that when a high-sensitivity CRP assay is used, serum CRP levels greater than 0.3 mg/dL indicate increased the relative risk of atherogenesis and future myocardial infarction.[167] The statistical strength of this is as robust as, but not more robust than, established risk factors such as hypertension, diabetes, and hypercholesterolemia.[168-170] The primary unanswered questions remain: Why does CRP predict myocardial infarction? Is it a pathogenic mediator itself?

The observation that CRP is associated with many noninflammatory conditions (e.g., low levels of physical activity, low intake of fruits and vegetables, a variety of other "unhealthy" diets, smoking, hypertension, obesity, sleep deprivation, and low alcohol intake) indicates that classic inflammation does not invariably underlie a CRP response.[171] Many of these CRP-associated conditions are known to be risk factors for cardiovascular disease, confounding the situation and suggesting that CRP predicts myocardial infarction because of its association with these risk factors. In addition, elevated CRP may not reflect inflammation, but rather a response to the presence of distressed, metabolically disturbed cells.[171] This reverse causation offers a potential explanation of the laboratory result, because atherosclerosis might trigger an elevation in CRP.

Nevertheless, CRP has been known for many years to bind to low-density lipoprotein (LDL) and to activate complement—a potentially pro-inflammatory response; it has also been detected in atherosclerotic plaques.[29,172-174] These observations have raised the possibility that CRP may play a direct causal role in coronary heart disease. Proatherogenic effects secondary to CRP injections given to mice, however, may have been caused by contaminants in commercial CRP preparations, not by CRP itself.[175] Because statin drugs lower CRP and LDL, some consider their effects to provide indirect evidence of a causal role of CRP. In the justification for the use of statins in prevention: an intervention trial evaluating rosuvastatin (JUPITER) trial, patients with normal LDL and elevated CRP were prescribed rosuvastatin, 20 mg daily, or placebo, and were followed prospectively. Those in the treatment arm had significant reductions in major cardiovascular events.[176] However, whether the effects of the study can be solely dependent on CRP reduction remains unclear; alternative explanations have been suggested, including the question of the importance of lowering LDL even among patients with healthy levels.[177] Whether to target CRP levels in cardiovascular disease is an ongoing topic of intense debate.

Because no CRP inhibitor drugs are available to directly measure the effect of lowering the protein, recent studies have centered on observing patients with genetic variations that result in different baseline levels of CRP. To date, results have been conflicting with regard to the role of genetically determined CRP levels in coronary heart disease.[178-182]

Epidemiologic studies that describe an association of CRP levels with morbidity and mortality in many chronic diseases, and even in normal aging, have become a cottage industry. It is important to remember that these are observational population studies. Although such associations may have broad and intriguing implications, particularly at a societal level, they reflect probabilities. This limits their clinical value when they are applied to individual patients.

CHAPTER 58

# Imaging in Rheumatic Diseases

Mikkel Østergaard • Robert G.W. Lambert • Ho Jen • Walter Grassi

## KEY POINTS

**Practical Use of Imaging in Inflammatory Joint Diseases**

**A. Peripheral joints**

**Use in clinical practice:**

- **To establish a diagnosis of rheumatoid arthritis (RA): radiography, magnetic resonance imaging (MRI), ultrasonography**
- **To assist with the diagnostic workup in suspected, but not definite, inflammatory joint disease and early, unclassified inflammatory joint disease (by detection of the presence or absence of synovitis, enthesitis, or bone erosions, among other conditions): radiography, MRI, ultrasonography**
- **To monitor disease activity: MRI, ultrasonography**
- **To monitor structural joint damage: radiography, MRI**
- **To assist with the prognostic stratification of patients with early RA: radiography, MRI, (ultrasonography*), (DXR*)**
- **To help define the presence or absence of true remission: MRI, ultrasonography**
- **To guide aspirations and injections in joints, bursae, and tendon sheaths: ultrasonography**

**Use in clinical research:**

- **To assess structural joint damage in RA trials: radiography, MRI**
- **To assess the anti-inflammatory effectiveness of a new compound: MRI, ultrasonography**
- **For pretrial selection of the patients most likely to progress: radiography, MRI**

**B. Axial joints**

**Use in clinical practice:**

- **To establish a diagnosis of ankylosing spondylitis (AS)/spondyloarthropathies (SpA): radiography/radiography and MRI**
- **To monitor disease activity: MRI**
- **To monitor structural joint damage: radiography, MRI, (CT†)**

**Use in clinical research:**

- **To assess structural progression in AS/SpA trials: radiography, MRI**
- **To assess the anti-inflammatory effectiveness of a new compound: MRI**
- **For pretrial selection of the patients most likely to progress: radiography, MRI**

*Promising, but more data needed.
†CT allows this but cannot be used because of radiation exposure.

For decades, imaging in rheumatology has been synonymous with conventional radiography (CR). However, new imaging modalities, including magnetic resonance imaging (MRI) and ultrasonography, have dramatically increased the amount and scope of information obtainable by imaging. In rheumatology, imaging may be used for multiple reasons that include establishing or confirming the diagnosis, determining the extent of disease, monitoring change in disease (e.g., activity and structural damage), selecting patients for specific therapies (e.g., surgery or injections), identifying complications of disease or treatment, and assessing therapeutic efficacy in trials. These different contexts may require different imaging approaches.

This chapter focuses on the inflammatory joint diseases, such as rheumatoid arthritis (RA), psoriatic arthritis (PsA), ankylosing spondylitis (AS), other types of axial spondyloarthritis (SpA), gout, and osteoarthritis (OA). Other aspects, including nuclear medicine and capillaroscopy in connective tissue diseases and vasculitides are also briefly discussed. The reader is referred to the chapters on the individual diseases for imaging aspects of other rheumatologic diseases, and to textbooks of musculoskeletal radiology[1] for more detailed descriptions of the different imaging modalities, including the technical aspects. This chapter outlines the virtues of CR and describes its current major importance in diagnosis and follow-up of rheumatologic diseases, but also, by putting emphasis on newer imaging modalities, particularly MRI and ultrasonography, stresses that rheumatology has entered a time of exciting and expanding therapeutic as well as imaging possibilities.

## CONVENTIONAL RADIOGRAPHY

### KEY POINTS

**Radiography is relatively inexpensive, easily available, and reliable.**

**Radiography provides information on bone damage and, indirectly through joint space narrowing, on cartilage damage, although radiography is neither sensitive nor specific for soft-tissue change.**

**Radiography findings are important parts of the classification criteria for many rheumatic disease, including RA, AS, SpA, PsA, and OA.**

Videos available on the accompanying ExpertConsult website.

**Radiography should most often be the first imaging investigation in arthritis because the significance of positive and negative findings is well known.**

**Radiography can be used to follow structural damage progression in inflammatory and degenerative joint diseases but is less sensitive to change than MRI.**

**The main disadvantage of radiography is its low sensitivity, particularly for soft tissue changes.**

The first roentgen ray image was an "x-ray" of the hand. Since then, imaging of musculoskeletal structures has been an important part of conventional radiography (x-ray).[1] The simple radiography is relatively cheap, available worldwide, and produces an image that is almost identical, regardless of technical parameters or whether the image is analogue or digital. The reliability of the image means that despite the limitations of radiography, advances in clinical practice can rely on the good old x-ray, knowing that it is largely independent of technologic advances. For many years to come, radiographs will appear much the same.

## Technical Aspects

The conventional radiograph is a two-dimensional summation image that is dependent on variable absorption of x-rays by different tissues for its inherent contrast. It has a very high spatial resolution that is rarely surpassed by other modalities, but radiography only offers high-contrast between a limited number of structures: bone (calcium), soft tissue, and air. Fat is visible as a separate density, but the distinction between soft tissue and fat is often subtle, and radiography cannot distinguish among the other soft tissues because cartilage, muscle, tendon, ligament, synovium, and fluid all appear to have the same density. These characteristics point to the radiograph's inherent advantages and disadvantages.[1,2]

In its favor, radiographs show skeletal structure very well, and because they are summation images, they allow excellent overall assessment of skeletal trauma and alignment. The limited number of images produced facilitates rapid review, and the high bone-soft tissue contrast often produces radiographic manifestations of disease in specific patterns that make the test particularly useful in daily clinical practice. The greatest disadvantage of radiography is its inherent lack of soft tissue contrast, which makes it insensitive for the detection of soft tissue abnormalities. The first radiographic sign of inflammatory arthritis may be permanent structural damage (bony erosion); in degenerating joints, cartilage damage is not usually visualized until sufficient overall cartilage loss allows approximation of the bone ends, resulting in joint space narrowing.

Although radiographs use ionizing radiation, they should be regarded as relatively safe, especially in older patients. An exception may be spine radiography, in which higher doses are used to penetrate the trunk, and in a younger population, MRI offers a safer and more informative alternative. In most examinations, two or more projections are required to adequately visualize the joint in question, and radiographic quality is improved by strict adherence to standard imaging protocols.

## Rheumatoid Arthritis

RA is the archetypal inflammatory joint disease, and it primarily targets synovium and peripheral joints. It is a systemic inflammatory disorder in which the typical clinical manifestations are usually symmetric, and thus the radiographic signs usually follow this pattern. As in all of radiology, the observed distribution of disease is often characteristic of the underlying cause. In RA, the metacarpophalangeal (MCP) and proximal interphalangeal (PIP) joints of the hands and the wrists, and the metatarsophalangeal (MTP) joints of the feet are most often involved.[1,2]

Juxta-articular osteoporosis is a characteristic feature of RA, best seen in early disease in the small peripheral joints. In later stages of disease, generalized osteoporosis is usually present and is exacerbated by joint disuse. Erosion of bone (Figure 58-1) is a characteristic feature of RA that usually appears first at the margins of the joint, where the proliferating synovium lies directly on the surface of the bone between the edge of the cartilage-covered articular surface and the capsular attachment—the "bare areas." These marginal erosions may be subtle and first appear as disruptions of the thin white cortical line, especially at the radial aspect of the metacarpal heads, where they may be best seen on dedicated radiographic projections, such as the ball-catcher's view of the hands. These erosive changes are a good indication of the aggressiveness of the arthritis. In large joints, synovial proliferation may be very severe before bony erosion is detectable on radiography. This is especially notable in the knee, where pain and swelling caused by arthritis and bursitis occur long before erosion occurs. In addition to bare-area erosions, two other types of erosions have been described in RA. *Compressive erosion* refers to remodeling of inflamed and osteoporotic bone, with gradual invagination of one bone into another typified by protrusio acetabuli of the hip (see Figure 58-1E). *Surface erosion* of bone may also be seen, usually as a result of inflammation of an adjacent tendon sheath. A typical location for this is at the outer margin of the ulnar styloid process, secondary to extensor carpi ulnaris tenosynovitis.

Joint space involvement is characteristic in RA.[1,2] In many cases, the inflammatory processes result in progressive destruction of articular cartilage, which in turn causes the radiographic finding of concentric joint space narrowing. This condition is usually diffuse in RA as all of the cartilage is involved at the same time, and this feature may allow for differentiation from the focal or asymmetric type of joint space loss that occurs with degenerative disorders. Occasionally, cartilage destruction precedes synovial erosion of bone. Continued cartilage damage may result in partial or complete fibrous ankylosis, but progression to bony ankylosis is uncommon, although it may occur in end-stage disease in the wrist or midfoot. Subchondral radiolucent areas are common in RA and are often referred to as *cysts*, *geodes*, or *pseudocysts*. They may develop as a result of intraosseous extension of pannus, injury to the bone of any kind, or true intraosseous rheumatoid nodules. Mechanical factors accentuate their development, and very large cystic lesions may be seen in the elbow, femoral neck, or knee, and occasionally will precipitate pathologic fractures.

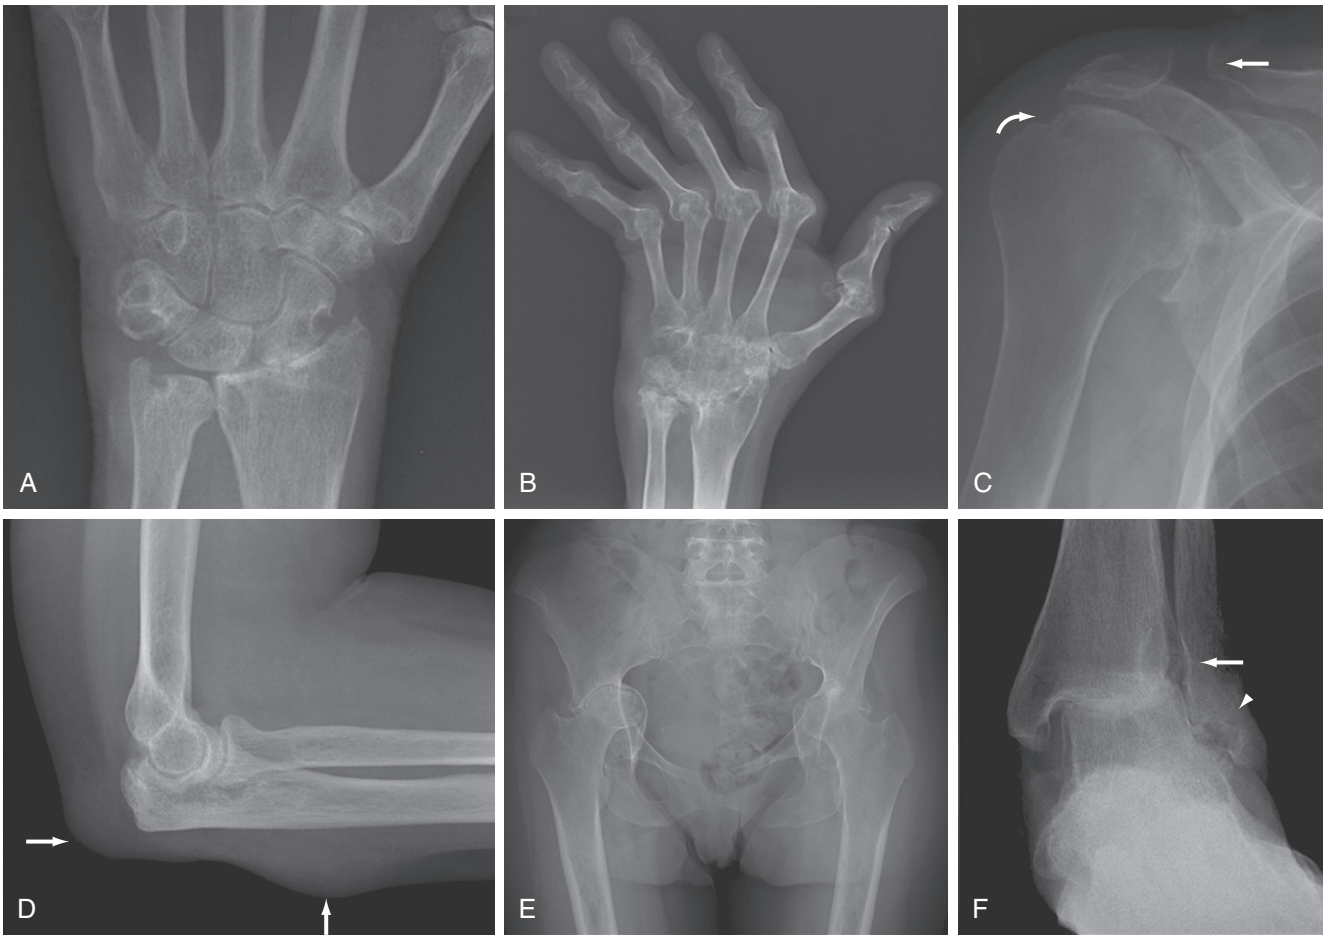

**Figure 58-1 Rheumatoid arthritis (radiographs). A,** Multiple typical bone erosions are seen (e.g., in triquetrum, pisiform, scaphoid, radius, and ulnar styloid process). Diffuse cartilage loss also is evident in the radiocarpal compartment. **B,** Severe ulnar deviation is present at the metacarpophalangeal joints with extensive erosions. Severe erosion and bony ankylosis are seen in the wrist. **C,** Posterior oblique view of a shoulder shows severe glenohumeral joint space narrowing with marginal erosion and cystic change of the humeral head adjacent to the greater tuberosity *(curved arrow)*. Elevation of the humeral head with respect to the glenoid indicates chronic rotator cuff tear. Tapering of the distal end of the clavicle and widening of the acromioclavicular joint *(straight arrow)* are also evident. **D,** Rheumatoid nodules appearing as lobulated subcutaneous soft tissue swellings *(arrows)* at the extensor surface of the elbow and forearm. **E,** Bilateral protrusio acetabuli. The medial acetabular margins protrude into the pelvis. Severe accompanying cartilage loss has occurred. **F,** Ankle with diffuse loss of cartilage space with erosions of the fibula (*arrow* and *arrowhead*). The hindfoot is in valgus alignment.

Symmetric soft tissue swelling around the small joints of the hands or feet is often the first clinical and radiographic sign of RA. The soft tissue swelling is caused by joint effusion, synovial proliferation, and periarticular inflammation, but the radiographic findings are nonspecific. Radiographs are much less sensitive for such changes than MRI and ultrasonography. Eccentric soft tissue swelling may be the result of adjacent bursitis, tenosynovitis, or rheumatoid nodules. Involvement of tendons and tendon sheaths is common; however, the soft tissue changes are usually poorly visualized and thus are of lesser diagnostic importance.

Joint malalignment and deformity (see Figure 58-1) are very common in RA and occur because of laxity and disruption of capsule, ligaments, and tendons. The deformities are most prevalent in the hand, wrist, foot, and neck. Note that these malalignments may be transient and can be reduced depending on the positioning for the radiographs. Late-stage disease is associated with severe deformity, as seen in arthritis mutilans.[1,2]

## Spine

Cervical spine involvement is common in RA and merits specific attention. It occurs mainly after several years of disease in rheumatoid factor $(RF)^+$ patients with severe peripheral RA, and may cause severe pain, instability and, ultimately, spinal cord compression.[3] Prevalences of radiologic cervical involvement as high as 70% have been reported, but are much lower in recent studies in accordance with the fact that intensive disease-modifying antirheumatic drug (DMARD) therapy has been shown to reduce cervical radiological progression.[4]

The upper cervical region is most affected, although abnormalities throughout the cervical spine are frequent (Figure 58-2). Upper cervical changes include odontoid process (dens) erosion and atlantoaxial subluxations (anterior, vertical [known as cranial settling], lateral, and posterior), whereas subaxial manifestations include abnormalities of apophyseal and discovertebral joints, subluxation, and dislocation.

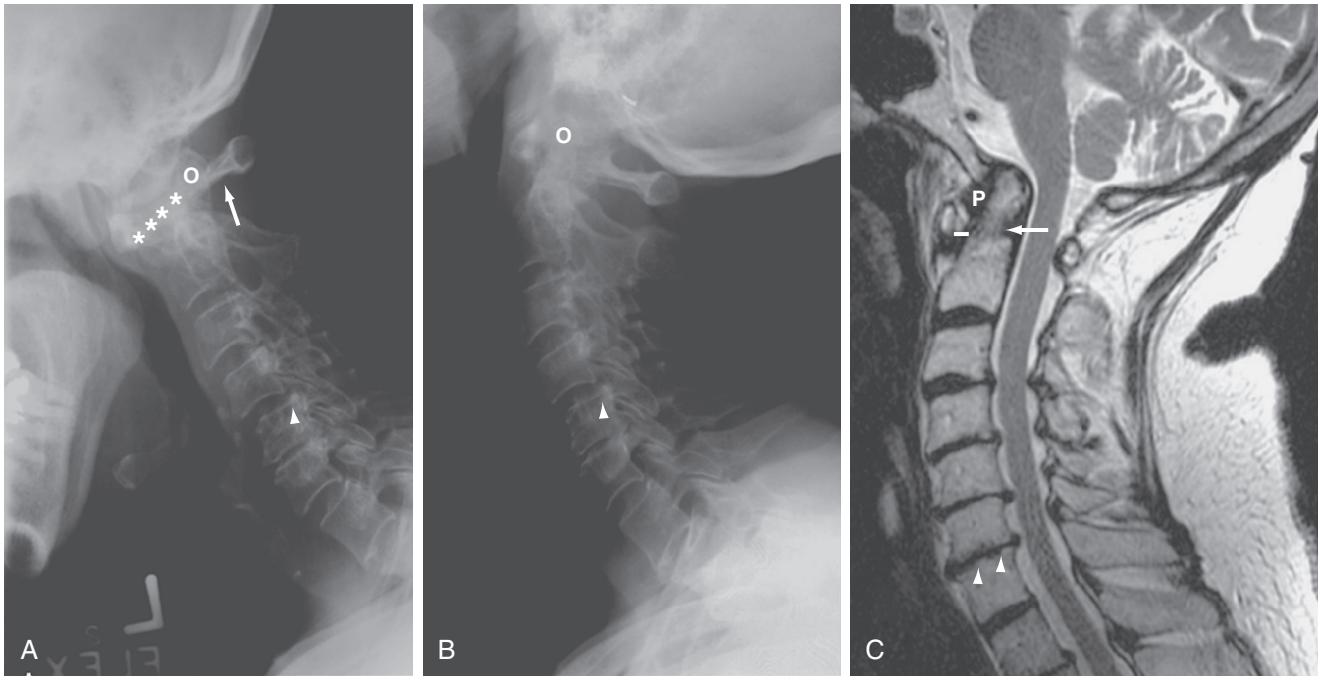

**Figure 58-2 Cervical spine in rheumatoid arthritis (RA) (radiography and MRI). A** and **B,** Radiography shows anterior atlantoaxial subluxation in RA. **A,** Lateral radiograph in flexion shows severe anterior atlantoaxial subluxation with a wide anterior atlantodental interval *(asterisks)* and a decreased posterior atlantodental interval *(arrow)*. **B,** Almost complete reduction of subluxation is noted on the lateral view in extension. There also is subaxial subluxation at the level of C4-C5 *(arrowhead)* with erosive changes in various facet joints. **C,** T2-weighted sagittal magnetic resonance (MR) image in RA shows low signal periodontoid pannus *(P)*. The odontoid *(O)* process appears irregular secondary to erosions *(arrow)*. The atlantodental distance shows mild widening *(solid line)*. There also is vertical subluxation without signs of cord compression. The anterior subarachnoid space is compromised by disk protrusions at multiple levels. Small erosions *(arrowheads)* are seen at the vertebral end plates at the C6-C7 level.

Adequate radiographic evaluation of the cervical spine requires lateral views in flexion and extension and should be performed in all patients with RA with neck pain. The flexion-extension views are especially important for demonstration of the degree of atlantoaxial instability.

Atlantoaxial subluxation is caused by laxity or rupture of the transverse ligament. The characteristic finding is anterior subluxation (i.e., abnormal separation between the anterior arch of the atlas and the odontoid process of the axis). Reports of the exact lower limit of abnormal distance vary, but a distance of greater than 2.5 mm is considered abnormal, or if the distance changes significantly between flexion and extension.[1] Cranial settling is diagnosed by radiographic measurement of the relationship between the tip of the odontoid process and landmarks at the base of the skull.[1] It may lead to protrusion of the dens through the foramen magnum and compression of neurologic structures. Significant atlantoaxial subluxations, particularly when accompanied by clinical findings, may require surgery.

Subaxial involvement is also frequent, and involves varying degrees of bone erosion, joint space narrowing and subluxation of facet joints, as well as disk space narrowing and spinous process erosions. Subaxial subluxations may also lead to neurologic deficits.[1]

MRI is useful for supplementary information on cervical spine involvement (see Figure 58-2C), including spinal cord compression (see MRI section).

### Use in Diagnosis, Monitoring, and Predicting Outcome

**Diagnosis.** Characteristic radiographic findings are part of the American College of Rheumatology (ACR) 1987 classification criteria for RA.[5] Radiography also has a role in the recent ACR/European League against Rheumatism (EULAR) 2010 classification criteria because patients who display bone erosions typical for RA plus at least one clinically swollen joint fulfill the criteria and are classified as having RA.[6,7] Radiography can help to differentiate RA from other joint conditions, including OA, PsA, and neoplasm.[2] EULAR recommendations for the use of imaging, including radiography, in the clinical management of RA have recently been published (Table 58-1).[8]

**Monitoring.** In routine clinical management and in clinical trials of RA, radiographic evaluation focuses on joint space narrowing and bone erosions in hands, wrists, and forefeet as measures of structural joint damage.[9-11] Validated scoring methods of radiologic damage (the Larsen method and the Sharp method and their modifications) are available and extensively used in clinical trial.[10-12] The van der Heijde and Genant modifications of the Sharp score are generally considered the methods most sensitive to change, but are also the most time consuming.[13] For clinical practice, the less time-consuming Simple Erosion Narrowing Score (SENS), based on counting joints with bone erosion and joints with joint space narrowing, is available,[14,15] but it is seldom used.

**TABLE 58-1** EULAR Recommendations for the Use of Imaging in the Clinical Management of Rheumatoid Arthritis*

| |
|---|
| When there is diagnostic doubt, conventional radiography, ultrasonography, or MRI can be used to improve the certainty of a diagnosis of RA in addition to clinical criteria alone.† |
| The presence of inflammation seen with ultrasonography or MRI can be used to predict the progression to clinical RA from undifferentiated inflammatory arthritis. |
| Ultrasonography and MRI are superior to clinical examination in the detection of joint inflammation; these techniques should be considered for more accurate assessment of inflammation. Conventional radiography of the hands and feet should be used as the initial imaging technique to detect damage. However, ultrasonography and/or MRI should be considered if conventional radiographs do not show damage and may be used to detect damage at an earlier time point (especially in early-stage RA). |
| MRI bone edema is a strong independent predictor of subsequent radiographic progression in early RA, and should be considered as a prognostic indicator. Joint inflammation (synovitis) detected by MRI or ultrasonography as well as joint damage detected by conventional radiographs, MRI, or ultrasonography can also be considered for the prediction of further joint damage. |
| Inflammation seen on imaging may be more predictive of a therapeutic response than clinical features of disease activity; imaging may be used to predict response to treatment. |
| Given the superior detection of inflammation by MRI and ultrasonography versus clinical examination, they may be useful in monitoring disease activity. |
| The periodic evaluation of joint damage, usually by radiographs of the hands and feet, should be considered. MRI (and possibly ultrasonography) is more responsive to change in joint damage and can be used to monitor disease progression. |
| Monitoring of functional instability of the cervical spine by lateral radiograph obtained in flexion and neutral positions should be performed in patients with clinical suspicion of cervical involvement. When the radiograph is positive or specific neurologic symptoms and signs are present, MRI should be performed. |
| MRI and ultrasonography can detect inflammation that predicts subsequent joint damage, even when clinical remission is present and can be used to assess persistent inflammation. |

*Recommendations are based on data from imaging studies that have mainly focused on the hands (particularly wrists, metacarpophalangeal and proximal interphalangeal joints). There are few data with specific guidance on which joints to image.[8]

†In patients with at least one joint with definite clinical synovitis, which is not better explained by another disease.

EULAR, European League against Rheumatism; MRI, magnetic resonance imaging; RA, rheumatoid arthritis.

**Predicting Outcome.** Early bone erosion correlates with poor long-term radiographic and functional outcome,[16] and early progression in radiographic erosion is related to future impairment in physical function.[17] In early undifferentiated arthritis, the presence of radiographic erosion increases the risk for persistent arthritis.[18] However, radiographic erosions are only present in a minority of patients with early-stage RA, with reported prevalences of 8% to 40% at 6 months,[19-23] and the absence of erosion in early disease is not necessarily associated with good outcomes. Thus, at this stage radiography is not effective for identifying future "non-progressors," (i.e., patients who will not show increasing structural joint damage).[24]

## Ankylosing Spondylitis

AS is the archetypal inflammatory joint disease that primarily targets fibrocartilage and the axial skeleton. Cartilaginous joints and sites of enthesis (tendon and ligament insertion) are involved early, and the characteristic involvement of the axial skeletal includes a predilection for the sacroiliac joints and all the articulations and entheses of the spine.

### Sacroiliac Joints

Erosion and ankylosis of the sacroiliac joints are the hallmarks of SpA.[1,25] Sacroiliitis is usually the first manifestation and is characteristically bilateral and symmetric in AS.[26,27] Early radiographic findings predominate on the iliac side of the cartilage compartment, with erosion of subchondral bone causing loss of definition of the articular surfaces, usually accompanied by varying degrees of adjacent osteoporosis and surrounding reactive sclerosis. Bone erosion may result in the radiographic observation of focal joint space widening (Figure 58-3A) and, as the disease progresses, definition of the joint is completely lost, with radiographic superimposition of erosion, sclerosis, and new bone formation which fills in the erosions and the original cartilaginous joint space. The joint may disappear completely in late-stage disease, with ankylosis and remodeling of the bone (see Figure 58-3B). The ligamentous compartment of the SI joint is frequently affected by bony erosion and entheseal proliferation, although these may be hard to see radiographically.[26,27]

### Spine

Traditional descriptions of the initial sites of spinal involvement are enormously influenced by the inability of radiography to adequately visualize many parts of the spine. Radiographic reports indicate that the lumbosacral and thoracolumbar junctions are first affected, whereas the MRI literature clearly indicates a predilection for early involvement of the midthoracic spine—an area that is extremely difficult to evaluate radiographically. The cervical spine is rarely affected first, but this can occur occasionally in women. Spinal disease rarely occurs in the absence of significant SI joint involvement.

The early radiographic manifestations of AS in the spine are most often caused by enthesitis at the edges of the discovertebral joints.[26] Focal sclerosis (the "shiny corner") and erosion (the "Romanus lesion") develop at the attachment of the annulus fibrosis to the anterior corner of the vertebral end plate and are characteristic features of early-stage AS (Figure 58-4A).[28] The anterior borders of vertebrae may appear straight or "squared" because of periosteal proliferation of new bone filling in the normal concavity or erosion at the anterosuperior and anteroinferior vertebral margins. This observation is much easier to make in the lumbar spine, where normal vertebrae are always concave anteriorly in comparison with the thoracic and cervical spine, where the normal contour is much more variable and may be square or occasionally convex.

The hallmark of spinal disease in AS is the development of characteristic bony spurs: syndesmophytes (see Figure

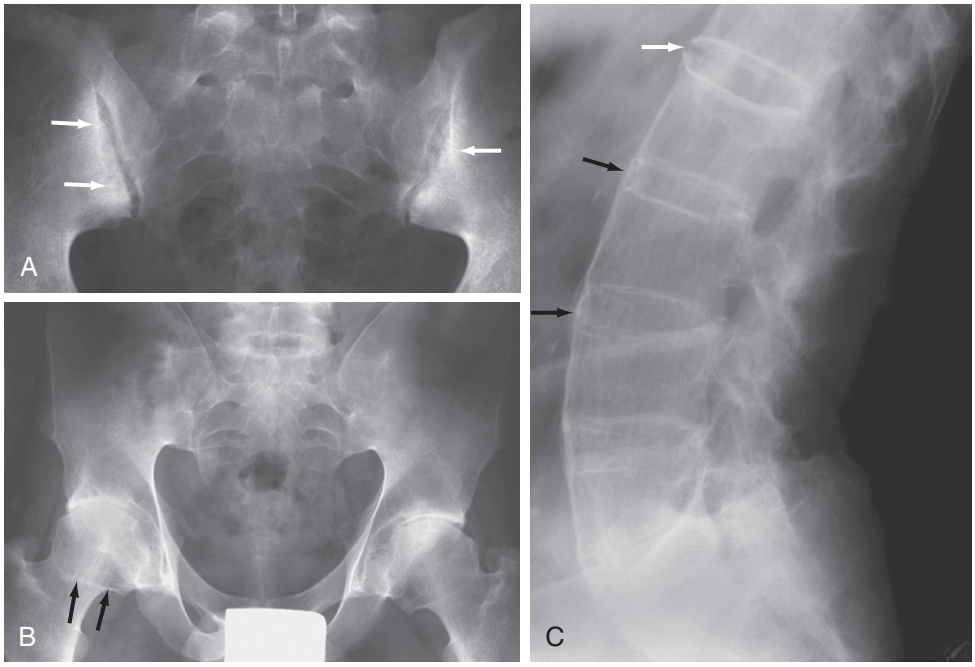

**Figure 58-3 Ankylosing spondylitis (radiograph). A,** Sclerosis *(arrows)* is seen along the iliac sides of the sacroiliac joints along with loss of portions of the iliac subchondral bone, indicating erosion. **B,** Bilateral hip joint space narrowing is present. A ring of osteophytes is noted at the synovial insertion *(arrows)* on each femoral head. The sacroiliac joints are fused (ankylosis). **C,** Syndesmophytes (*black* and *white arrows*), some of which extend from the edge of one vertebral body to the next (bridging syndesmophytes, ankylosis; *black arrows*), are seen is this lateral view of the spine.

58-3C). These spurs start as thin, vertically oriented projections of bone that develop from ossification within the outer fibers of the annulus fibrosus of the intervertebral disk. Syndesmophytes are radiographically visible on the anterior and lateral aspects of the spine starting from the corner of the vertebra. Progressive growth will bridge the intervertebral disk, causing ankylosis. Extensive syndesmophyte formation produces a smooth, undulating spinal contour—the "bamboo spine." The syndesmophytes that characterize AS must be differentiated from other spinal and paraspinal bone formations. Degenerative bony spurring in spondylosis deformans arises several millimeters from the discovertebral junction, is typically triangular in shape, and has a horizontally oriented segment of variable length at the point of origin. In diffuse idiopathic skeletal hyperostosis (DISH), bone formation in the anterior longitudinal ligament results in a flowing pattern of ossification that is usually thick, and the sacroiliac joints are not involved.

Erosion of the vertebral end plate is common in later stages of AS and may be focal or diffuse. It is also seen when pseudoarthrosis develops after a fracture in a previously ankylosed spine. Changes in the apophyseal joints are common and start with ill-defined erosion and sclerosis but may be hard to see. Capsular ossification or intra-articular bony ankylosis frequently occurs in late-stage disease (Figure 58-4). The ankylosed spine is very susceptible to fractures (see Figure 58-4C and D), which should always be suspected in case of unexplained pain exacerbations. Enthesitis at the interspinous and supraspinous ligamentous attachments is very common with bone formation causing whiskering and interspinous ankylosis.

### Use in Diagnosis, Monitoring, and Predicting Outcome

Although the modified New York Criteria are actually classification criteria, these criteria are the most commonly used to diagnose AS and are based on clinical features and radiographic sacroiliitis.[25] According to these criteria, AS may be diagnosed if, in addition to one clinical criterion, grade 2 sacroiliitis (minimal sacroiliitis: loss of definition of the joint margins, minimal sclerosis, joint space narrowing, and erosions) or higher occurs bilaterally, grade 3 (moderate sacroiliitis: definite sclerosis on both sides of the joint, erosions, and loss of joint space), or grade 4 (complete bony ankylosis) occurs unilaterally.[25] Because of the requirement for these radiographic structural changes, the duration of disease before diagnosis has been a median of 7 to 10 years.[29] The definitions of radiographic changes according to the New York Criteria are included in the Assessment of Spondyloarthritis International Society (ASAS) classification criteria for axial SpA,[30] the European Spondyloarthritis Study Group (ESSG) criteria for SpA,[31] and in the modified New York Criteria.[25] EULAR recommendations for the use of imaging, including radiographs, in the diagnosis and clinical management of SpA have recently become available (Table 58-2).[32]

Radiography of the spine is not included in the classification criteria but may be useful to follow structural disease progression in patients with spinal involvement. The bone changes seen in patients with axial SpA develop slowly and are often not present in patients with early-stage disease. In general, only minor changes can be observed in the first several years. Different scoring methods, all based on

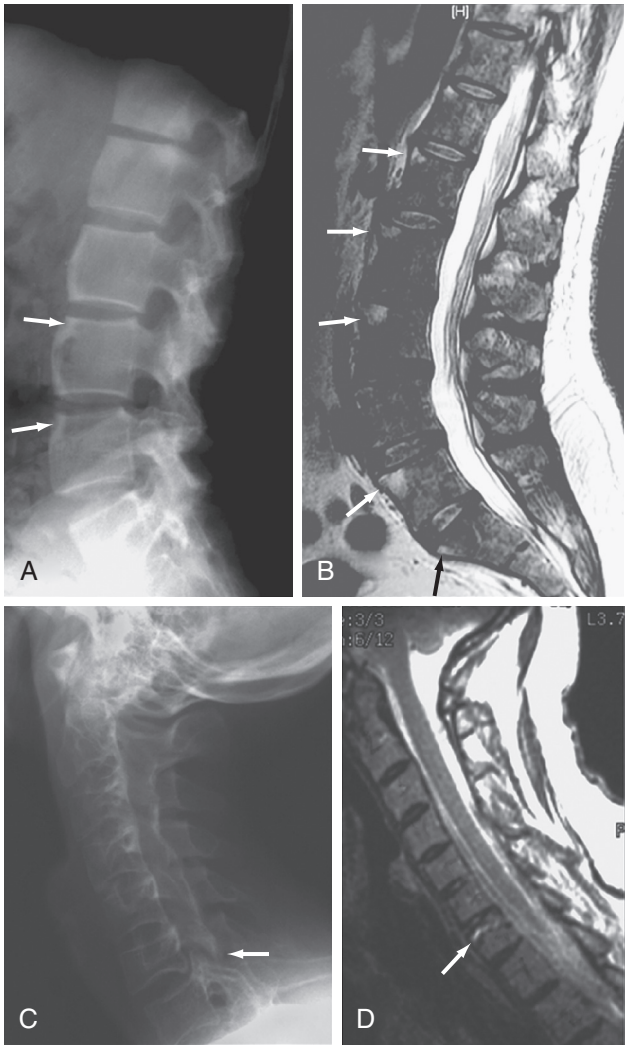

**Figure 58-4 Ankylosing spondylitis (radiography and MRI). A,** Lateral radiograph of the spine shows marked erosion at the vertebral margins has produced straight or slightly convex anterior vertebral surfaces ("squaring"). New bone formation has resulted in "shiny corners" *(arrows)*. The facet joints are fused. **B,** Sagittal fast spin echo T2-weighted MR image in another patient shows bone marrow edema at the anterosuperior corners of the vertebral bodies *(arrows)*, corresponding to early osteitis. **C** and **D,** Fracture in ankylosing spondylitis. **C,** Radiography shows disruption of the previously fused C6-C7 facet joints *(arrow)* and slight anterior subluxation. **D,** Sagittal T2-weighted MR image confirms a high signal fracture line *(arrow)* through the superior aspect of C7.

assessment of lateral views, have been developed to quantify changes in the spine of patients with AS: the Stoke AS Spine Score (SASSS), Bath AS Radiology Index (BASRI), and the modified Stoke AS Spine Score (mSASSS). A comparative study of the three methods concluded that all measures were reliable, but mSASSS was more sensitive to change.[33] These spine scores are primarily used in clinical research.

## Psoriatic Arthritis

The presentation of PsA is quite variable but is often distinctive. Peripheral joint involvement is common, and as many as half of patients with PsA have evidence of joint damage on radiographs within 2 years of presentation.[34] The hand and wrist are most often involved and are affected in as many as three quarters of patients with PsA. However, the pattern of joint involvement varies from patient to patient and also with time in individual patients. Radiographic appearances are usually asymmetric and may have a ray distribution, with the affected joints involving a single digit, including the DIP joints (Figure 58-5), which are seldom involved in RA. Clinically, this manifests as dactylitis, and is a common early feature of PsA. Osteoporosis is frequently absent, with the propensity for bone proliferation, which is a distinguishing feature of PsA. This may be in the form of periostitis of the shafts of the phalanges, which is sometimes the first radiographic manifestation, or irregular bony spurring at joints or entheses. Fluffy new bone formation adjacent to marginal joint erosions may result in a particularly characteristic "whiskering" appearance. Severe marginal erosion of the heads of metacarpals or phalanges may produce the appearance of a whittled pencil and, if combined with deep central erosion of phalangeal bases, is referred to as the "pencil-in-cup" appearance. Ankylosis of joints occurs frequently in advanced disease. Large joints are less often affected when the findings are usually similar to those of RA. Spinal involvement is frequent in patients with PsA. It may be seen in early-stage disease, and sacroiliitis may be demonstrable in as many as 75% of patients.[35] The changes may be extensive, and are more likely to be asymmetric than in AS.

### Use in Diagnosis, Monitoring, and Predicting Outcome

Although RA is characterized by mainly osteo-destructive lesions, in PsA both osteo-destructive and osteo-proliferative manifestations occur, which may even co-exist, not only in the same patient, but even in the same joint.[36] In particular, the osteo-proliferative lesions on radiography are characteristic, and are included in the new classification criteria (CASPAR) for PsA.[37] The presence of juxtaarticular new bone formation appearing as ill-defined ossification near joint margins (but excluding osteophytes) on radiographs of the hand or foot is one of five criteria.[37]

Structural joint damage on conventional radiography is an important outcome measure in PsA. Different radiographic scoring methods of peripheral joints have been developed (e.g., the Sharp–van der Heijde modified scoring method for PsA, which is a detailed scoring system for evaluating erosions and joint space narrowing) whereas osteolysis and pencil-in-cup phenomena are assessed separately.[13] Scoring systems are primarily used in clinical trials. No specific scoring systems for spine and sacroiliac joints in PsA exist, and can be monitored as in AS (see the subsequent text).

## Gout

A variety of microcrystals can deposit in and around the joints and induce an inflammatory response. In this chapter, the characteristics of gout (i.e., arthritis related to monosodium urate deposition) and of calcium pyrophosphate dihydrate (CPPD) crystal deposition disease will be discussed. The reader is referred to chapters on the individual diseases for description of the remaining conditions, such as calcium

**TABLE 58-2** EULAR Recommendations for the Use of Imaging in the Diagnosis and Management of Spondylarthritis in Clinical Practice

| |
|---|
| **Axial SpA: Diagnosis**<br>A. In general, conventional radiography of the SI joints is recommended as the first imaging method to diagnose sacroiliitis as part of axial SpA. In certain cases, such as young patients and those with short symptom duration, MRI of the SI joints is an alternative first imaging method.<br>B. If the diagnosis of axial SpA cannot be established based on clinical features and conventional radiography, and axial SpA is still suspected, MRI of the SI joints is recommended. On MRI, both active inflammatory lesions (primarily bone marrow edema) and structural lesions (such as bone erosion, new bone formation, sclerosis, and fat infiltration) should be considered. MRI of the spine is not generally recommended to diagnose axial SpA.<br>C. Imaging modalities other than conventional radiography and MRI are generally not recommended in the diagnosis of axial SpA.* |
| **Peripheral SpA: Diagnosis**<br>When peripheral SpA is suspected, ultrasonography or MRI may be used to detect peripheral enthesitis, which may support the diagnosis of SpA. Furthermore, ultrasonography or MRI might be used to detect peripheral arthritis, tenosynovitis, and bursitis. |
| **Axial SpA: Monitoring Activity**<br>MRI of the SI joints and/or the spine may be used to assess and monitor disease activity in axial SpA, providing additional information on top of clinical and biochemical assessments. The decision on when to repeat MRI depends on the clinical circumstances. In general, STIR sequences are sufficient to detect inflammation and the use of contrast medium is not needed. |
| **Axial SpA: Monitoring Structural Changes**<br>Conventional radiography of the SI joints and/or spine may be used for long-term monitoring of structural damage, particularly new bone formation, in axial SpA. If performed, it should not be repeated more frequently than every second year. MRI may provide additional information. |
| **Peripheral SpA: Monitoring Activity**<br>Ultrasonography and MRI may be used to monitor disease activity (particularly synovitis and enthesitis) in peripheral SpA, providing additional information on top of clinical and biochemical assessments. The decision on when to repeat ultrasonography/MRI depends on the clinical circumstances. Ultrasonography with high-frequency color or power Doppler is sufficient to detect inflammation, and the use of ultrasonography contrast medium is not needed. |
| **Peripheral SpA: Monitoring Structural Changes**<br>In peripheral SpA, if the clinical scenario requires monitoring of structural damage, then conventional radiography is recommended. MRI and/or ultrasonography might provide additional information. |
| **Axial SpA: Predicting Outcome/Severity**<br>In patients with AS (not nr-axSpA), initial conventional radiography of the lumbar and cervical spine are recommended to detect syndesmophytes, which predict development of new syndesmophytes. MRI (vertebral corner inflammatory or fatty lesions) may also be used to predict development of new radiographic syndesmophytes. |
| **Axial SpA: Predicting Treatment Effect**<br>Extensive MRI inflammatory activity (bone marrow edema), particularly in the spine in AS patients, might be used as a predictor of good clinical response to anti-TNF treatment in axial SpA. Thus, MRI might aid in the decision of whether to initiate anti-TNF therapy, in addition to clinical examination and CRP. |
| **Spinal Fracture**<br>When spinal fracture in axial SpA is suspected, conventional radiography is the recommended initial imaging method. If conventional radiography is negative, CT should be performed. MRI is an additional imaging method to CT, which can also provide information on soft tissue lesions. |
| **Osteoporosis**<br>In axial SpA patients without syndesmophytes in the lumbar spine on conventional radiography, osteoporosis should be assessed by hip DXA and AP-spine DXA. In patients with syndesmophytes in the lumbar spine on conventional radiography, osteoporosis should be assessed by hip DXA, supplemented by either spine DXA in lateral projection or possibly QCT of the spine. |

*CT may provide additional information on structural damage if conventional radiography is negative and MRI cannot be performed. Scintigraphy and ultrasonography are not recommended for diagnosis of sacroiliitis as part of axial SpA.

AP-spine, Anterior-posterior spine; AS, ankylosing spondylitis; CRP, C-reactive protein; CT, computed tomography; DXA, dual-energy x-ray absorptiometry; EULAR, European League against Rheumatism; MRI, magnetic resonance imaging; nr-axSpA, nonradiographic axial spondyloarthritis; SIJ, sacroiliac joints; SpA, spondyloarthritis; SOR, strength of recommendation; STIR, short tau inversion recovery; TNF, tumor necrosis factor.

hydroxyapatite crystal deposition disease, hemochromatosis, ochronosis, and Wilson's disease.

Radiography is not helpful to diagnose acute gouty arthritis because the findings are limited to the soft tissues and are nonspecific. Chronic tophaceous gout is an asymmetrical arthritis that frequently affects the feet, hands, wrists, elbows, and knees. The most common site of involvement is the first metatarsophalangeal (MTP) joint (Figure 58-6). The radiologic changes in long-standing gout are related to tophi and their effect on soft tissue and bone.[38]

Tophi appear as eccentric, nodular soft tissue masses around the joints with an amorphous increased density or patchy calcification.[38] Intraosseous tophi cause well-marginated subchondral cystic lucencies or intraosseous calcifications. Erosion of the adjacent bone is common at either the periosteal or endosteal surface. The erosions may be intra-articular, para-articular, or remote from the joint and are typically well defined with smooth sclerotic borders. An overhanging margin of bone at the edge of the erosion is a characteristic feature of gout. The joint space and bone density are usually preserved until late in the disease. Bursal inflammation commonly produces soft tissue swelling around the olecranon and in a prepatellar location.

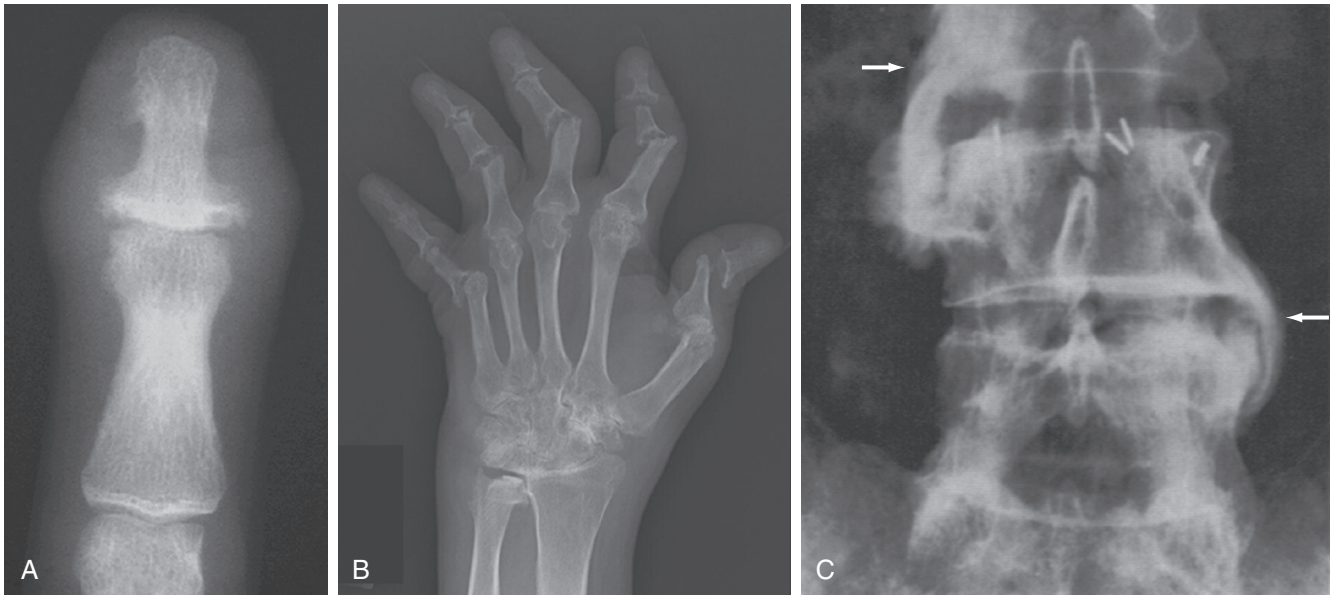

**Figure 58-5 Psoriatic arthritis (radiography). A,** Distal interphalangeal joint with classic radiographic findings, including soft tissue swelling, bone erosions with accompanying bone proliferation, and lack of osteoporosis. **B,** Arthritis mutilans resulting from psoriatic arthritis with destructive changes and joint deformity of the hand and pancompartmental ankylosis of the wrist. **C,** Psoriatic spondylitis. Thick asymmetric paravertebral ossifications *(arrows)*, which are characteristic of psoriatic spondylitis and reactive arthritis. *(From Resnick D, Niwayama G:* Diagnosis of bone and joint disorders, *Philadelphia, 1988, WB Saunders.)*

### Use in Diagnosis, Monitoring, and Predicting Outcome

The 1977 Criteria for the Classification of Acute Arthritis of Primary Gout[39] include the conventional radiographic features of asymmetric swelling and subcortical cysts without erosion. However, conventional radiographic features of acute gout have low clinical utility because of lack of sensitivity and specificity. In the chronic phase the characteristic pattern with asymmetrical, erosive polyarticular disease and tophi appearing as nodular soft tissue masses with amorphous increased density or patchy calcification may be diagnostically useful.

Recently a specific gout radiographic scoring method has been developed and validated and may improve sensitivity to change in longitudinal studies.[40] However, radiography is not a sensitive method for monitoring gout manifestations, compared with ultrasound and MRI, because inflammatory changes and tophi volumes cannot be assessed.[41]

## Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

The term *CPPD crystal deposition disease* refers to a variety of clinical situations, including asymptomatic crystal deposition, pseudogout, pyrophosphate arthropathy, and other, less frequent presentations, such as pseudo-RA. Chondrocalcinosis is a general term that refers to calcification of hyaline or fibrocartilage regardless of its etiology (Figure 58-7).

The acute attack of pseudogout is often a monoarthropathy, and typical radiographic findings of soft tissue swelling and joint effusion are non-specific, mimicking gout and infection. Often chondrocalcinosis is not radiographically visible. The radiographic changes in more chronic pyrophosphate arthropathy are very similar to OA with joint space narrowing, sclerosis, and subchondral cysts, with or without intra-articular or periarticular calcinosis.[42]

The patellofemoral joint and, in contrast to OA, the radiocarpal and the second and third MCP joints are typical sites of involvement in pyrophosphate arthropathy. The distribution is usually bilateral and may be symmetrical. In addition to the usual target sites, arthritic changes may be observed in non-weight-bearing joints and the sacroiliac joints.[43]

Pyrophosphate arthropathy may be associated with extensive and rapid subchondral bone collapse and fragmentation with intra-articular loose bodies, resembling neuropathic osteoarthropathy (pseudo-Charcot). Tumorous CPPD crystal deposits that resemble gouty tophi are observed occasionally, most frequently in digits, and are referred to as *tophaceous pseudogout*.[44]

## Septic Arthritis

Septic arthritis is usually monoarticular and typically associated with rapid onset of symptoms, systemic illness, obvious local clinical signs, and laboratory evidence of acute inflammation. The earliest clinical sign is symmetrical soft tissue swelling around a joint because of soft tissue edema, hypertrophied synovium, and joint effusion. However, this may be hard to discern on radiography, and periarticular osteopenia may be the first radiographic feature. Initial widening of the joint space may be seen, such as in septic arthritis of the pediatric hip. Marginal erosions develop quickly and have a similar appearance to other forms of erosive inflammatory arthritis. While the infection progresses, hyaline cartilage and the subchondral cortex are rapidly destroyed with progressive narrowing of the joint space (Figure 58-8). In late stages, ankylosis of the joint may be seen. Adjacent

**Figure 58-6** **Tophaceous gout (radiography, computed tomography [CT], and MRI). A,** Radiography of forefoot in tophaceous gout. Extensive bone destruction is seen at the first metatarsophalangeal (MTP) joint with overhanging edges *(arrowhead)* and soft tissue swelling. Smaller erosions are present involving the first tarsometatarsal and second MTP joints *(arrows)*. **B,** CT scan shows hyperdense tophus around the extensor digitorum muscle *(arrow)*, with smaller deposits around the other extensor tendons. Axial precontrast **(C)** and coronal short tau inversion recovery **(D)** MR images show a large tophus *(arrow)* medial to the first metatarsal bone. Ca, Calcaneus; Na, navicular. *(**C** and **D**, Courtesy Professor Fiona McQueen, Auckland, New Zealand).*

osteomyelitis occurs with increasing frequency while the infection becomes chronic. With granulomatous infections, the characteristic triad (Phemister's triad) of radiographic findings are marked osteoporosis, marginal erosions, and absent or mild joint space narrowing. Periostitis and bone production are less common.

### Use in Diagnosis, Monitoring, and Predicting Outcome

Radiography should be routinely performed but is insensitive for diagnosis. When there is clinical suspicion of septic arthritis, joint aspiration should be performed without delay.

The utility of radiography is limited in septic arthritis with immediate joint aspiration (directly or by image guided techniques) required for early diagnosis and more advanced imaging techniques required for assessment of associated osteomyelitis or other complications.[45] However, radiography should still be routinely performed because it may assist in interpretation of other studies and still offers a satisfactory overall assessment of bone morphology and background disease.

**Osteoarthritis.** OA primarily targets hyaline cartilage, and its distribution is profoundly influenced by mechanical factors. OA is typically asymmetrical in distribution both within and between joints. The most characteristic sites of osteoarthritis include the hips, knees (Figure 58-9), proximal and distal interphalangeal joints of the hand, first carpometacarpal and trapezioscaphoid joints of the wrist (Figure 58-10), and first metatarsophalangeal joints.[1]

Joint space narrowing caused by thinning of hyaline cartilage is a key feature of OA. Unlike the inflammatory

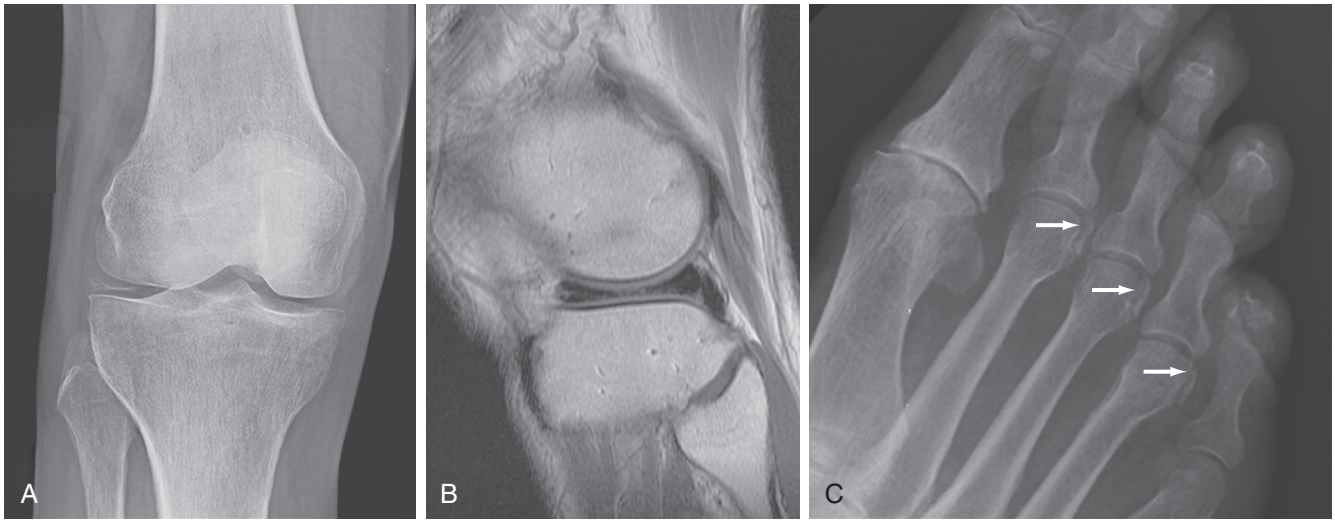

**Figure 58-7 Calcium pyrophosphate dihydrate crystal deposition disease (radiography and MRI).** Radiography of the knee **(A)** shows linear calcification within the lateral meniscus, whereas sagittal proton density MRI **(B)** of the same patient shows increased signal within the lateral meniscus, corresponding to chondrocalcinosis. **C,** Radiography of forefoot shows cartilaginous and capsular calcifications *(arrows)* within second through fourth metatarsophalangeal joints. A nondisplaced fracture of the fourth metatarsal neck is noted.

arthropathies, the resultant narrowing of the radiographic joint space is asymmetric, with cartilage thinning more pronounced in areas subject to greater mechanical stress, such as in one compartment of the knee. Accurate assessment of cartilage loss is hugely influenced by radiographic projection, particularly in the lower limbs. Sensitive detection of cartilage thinning requires apposition of the most affected surfaces, which requires the joint to be optimally positioned with sufficient mechanical stress to bring the surfaces into contact. In the knee, for example, angular deformity tends to reduce on supine radiography and severe cartilage loss may not be detected at all (see Figure 58-9). Bilateral weight-bearing projections are more consistent for the detection and measurement of cartilage loss and the erect extended anterior-posterior (AP) view is has been established as the preferred projection for diagnostic utility. However, no view is completely reliable until there is global loss of cartilage in late-stage disease. Weight-bearing in flexion is the most sensitive projection for cartilage thinning in the knee and the most reliable for detection of change, although the ideal degree of flexion for a specific individual varies depending on the distribution of cartilage loss (see Figure 58-9).[46,47]

Osteophytes are the most characteristic abnormality of OA, being more specific than joint space narrowing, and are often the first radiographic sign of the disease. They start as osseous metaplasia of the hyaline cartilage best seen at the articular margins but also occurring centrally on the articular surface. They can become large and often dominate the radiographic appearance. Thus, osteophytes are the key criterion to define presence of OA.[48]

Bone density is usually normal or sclerotic. Bone erosion does not occur except at the articular surface in late disease or occasionally earlier in the interphalangeal (IP) joints in inflammatory OA.

The radiographic appearance of periarticular soft tissues is relatively normal in OA. Synovitis and effusion do occur but only rarely dominate the radiographic presentation.

Some deformity is common, but tends to occur in particular joints such as the thumb and knee. The deformity is primarily caused by the asymmetric loss of cartilage and bone, resulting in malalignment or subluxation.

### Use in Diagnosis, Monitoring, and Predicting Outcome

Conventional radiography is the standard method for diagnosis and follow-up of OA. Radiographic changes are key in the ACR criteria for classification of OA. A patient with radiographic osteophytes and knee pain, and who is older than 50 years, has had stiffness for less than 30 minutes, or has crepitus should be classified with OA.[48] However, newer imaging modalities, in particular MRI, now provide additional information which is used in clinical trials and to understand the disease.

Various scoring systems have been developed to grade the severity of OA. Among the most well-known is the Kellgren and Lawrence five-point scale, which has been widely used in OA research studies.[49] Further atlas-based scoring systems have been developed, which provide more accurate discrimination among individual radiographic features of OA.[49,50] Whichever system is used, the reliability is variable. In addition, quantitative measurement of joint space width as a surrogate for cartilage thickness has been used in research studies, particularly in cases of knee OA but also in the hip and hand, and is subject to the limitations discussed previously.

## COMPUTED TOMOGRAPHY

**KEY POINTS**

**Computed tomography (CT) is a tomographic radiographic imaging technique that visualizes calcified tissue with high resolution. CT is a standard reference to detect bone destruction.**

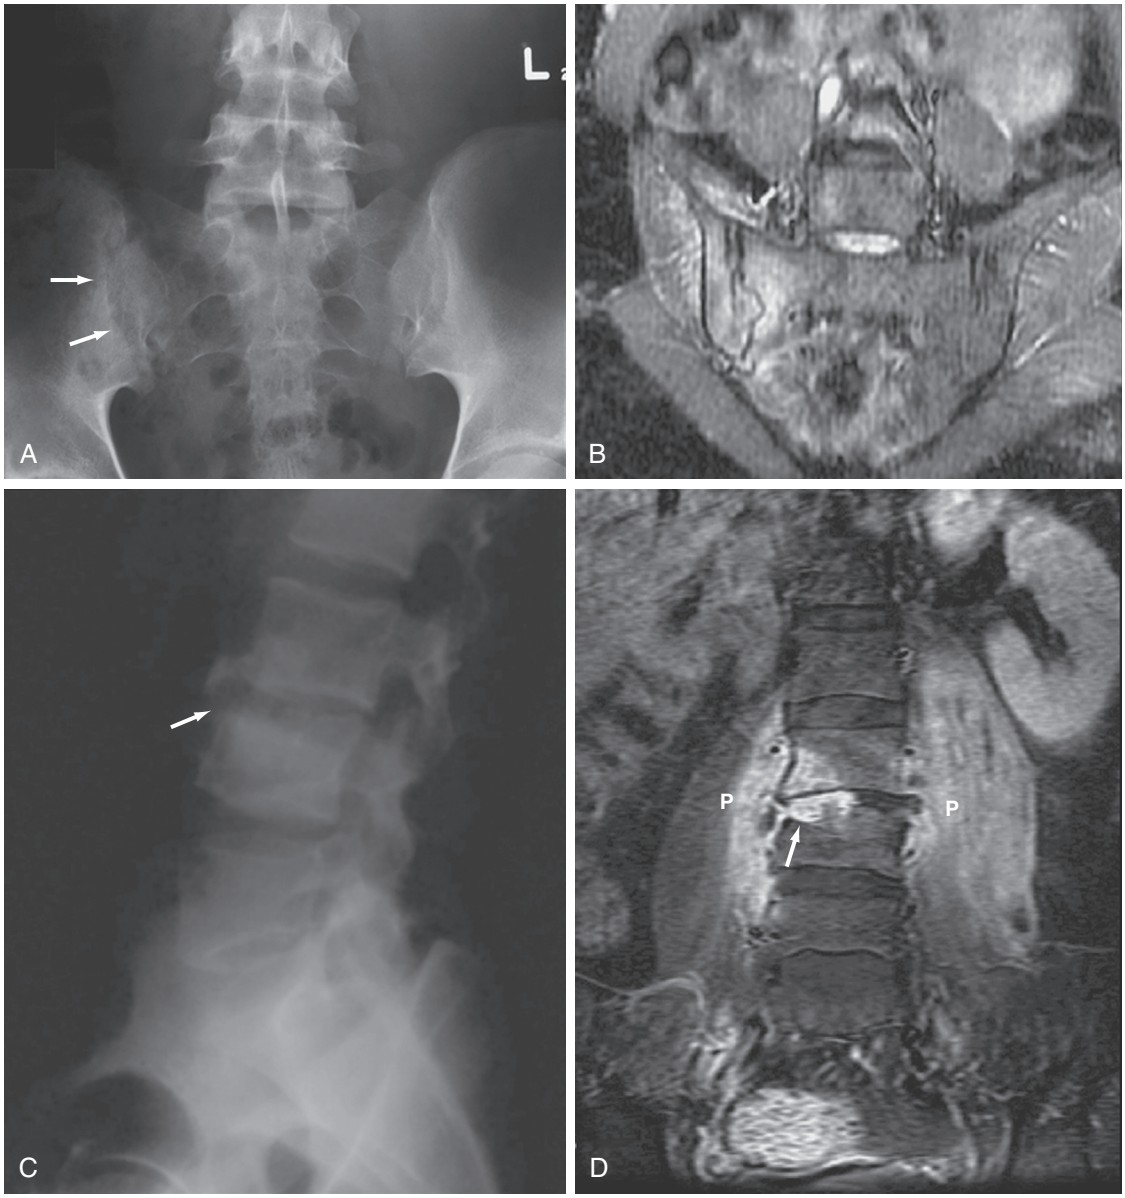

**Figure 58-8** **Septic arthritis (radiography and MRI). A,** Radiography in anteroposterior view of sacroiliac joints shows destruction of the right sacroiliac joint as part of septic arthritis *(arrows)*. **B,** In another patient, short tau inversion recovery (STIR) coronal MRI through sacroiliac joints shows erosive changes in the right sacroiliac joint with extensive bone marrow edema. **C** and **D,** Tuberculous spondylitis. **C,** Radiography of the lumbar spine in lateral view shows disk space narrowing at the L3-L4 level with destructive changes involving the superior end plate of the L4 vertebral body *(arrow)*. **D,** Coronal STIR MRI of the lumbar spine of the same patient confirms focal destruction of the L4 vertebral body *(arrow)*. Enlargement of both psoas muscles *(P)* with increased signal is noted, resulting from paraspinal extension of the infection.

**In rheumatology, CT is mainly useful to detect bone abnormalities in the axial skeleton (e.g., erosions, sclerosis, new bone formation, and fractures). CT is more sensitive for these purposes than radiography, and in most occasions MRI.**

**The role of CT of the axial skeleton is limited by the use of a relative high amount of ionizing radiation.**

**In practice, CT is rarely used unless radiography is unclear and MRI unavailable.**

**The main disadvantages of CT are the low sensitivity for soft tissue changes and the high patient exposure to ionizing radiation**

CT now has been available for 40 years, and each decade has brought further development in computing and engineering that has resulted in remarkable changes in the technology. Although still limited in soft-tissue contrast, CT offers fast and reliable acquisition, high resolution, and multiplanar capabilities that have enhanced its use in recent years. The modern CT scanner is a remarkable tool that will likely have an increasingly important role in arthritis imaging in the future.

## Technical Aspects

CT image acquisition is no longer restricted to the axial plane of imaging, and its multiplanar capability is so

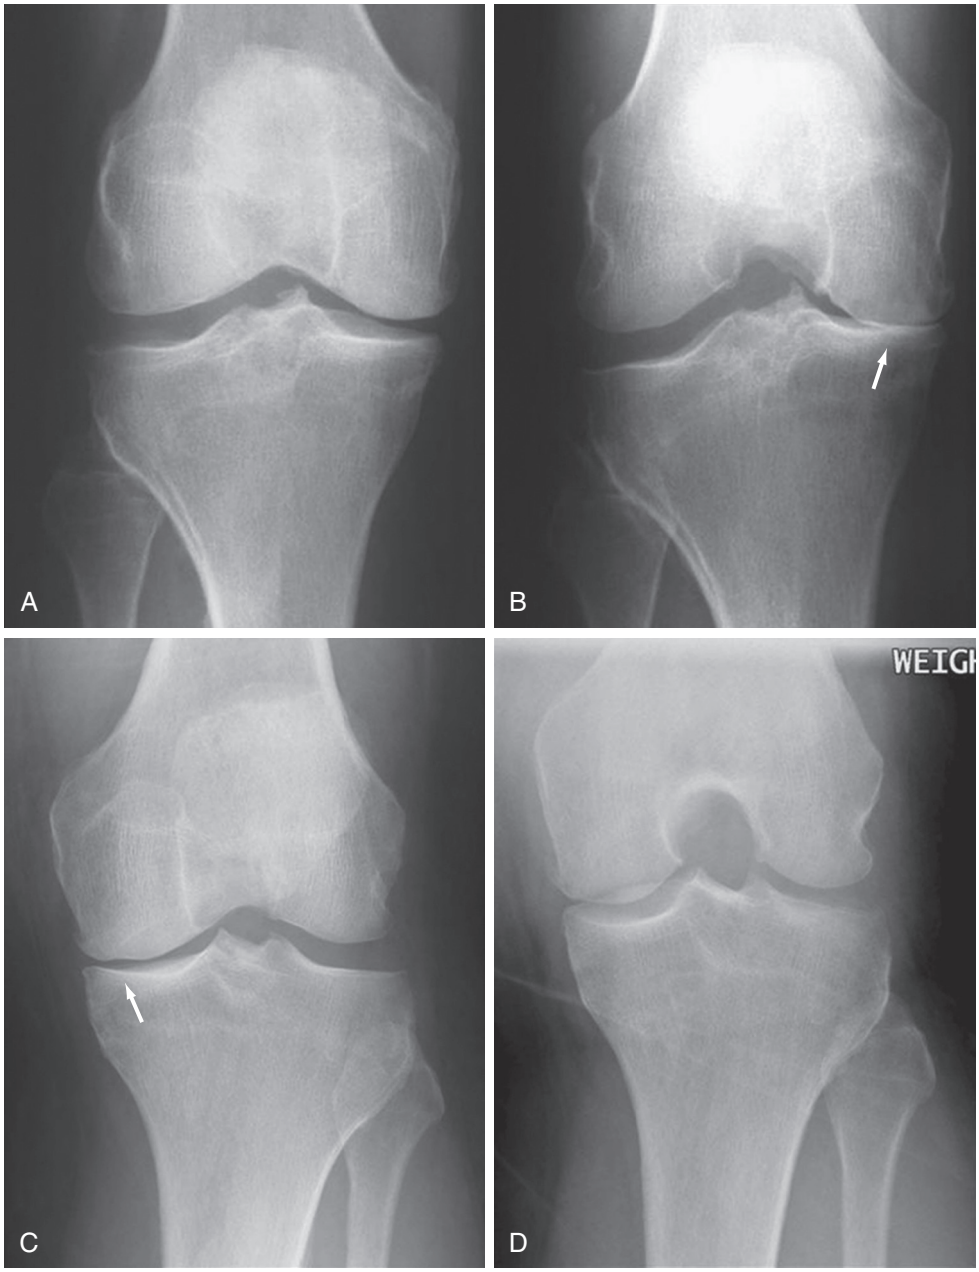

**Figure 58-9 Osteoarthritis of the knee (radiographs).** Non-weight-bearing radiographs of the knee frequently underestimate the severity of cartilage loss. A 59-year-old man with pain and suspected osteoarthritis had supine anteroposterior (AP) **(A)** and erect weight-bearing AP **(B)** radiographs of the knee. The supine view demonstrates mild osteophytosis and possible subtle joint space narrowing in the medial compartment, whereas on the weight-bearing view, severe medial joint space narrowing is present, indicating severe cartilage damage *(arrow)*. Usually the weight-bearing semi-flexed view is most sensitive to joint space narrowing (cartilage loss) but this is unpredictable: In a 53-year-old man, the erect AP view **(C)** shows more severe joint space narrowing *(arrow)* than is seen on the weight-bearing semi-flexed view **(D)**.

versatile that many CT scans of the body are now interpreted primarily from coronal or sagittal images in the same way as MRI. The data acquisition is so fast that patient motion is rarely a problem because CT scans are now routinely acquired in a few seconds. In fact, CT is often faster than multiple radiographs. Complex requirements for patient positioning in musculoskeletal CT are now largely irrelevant because almost all studies can be reconstructed to eliminate positioning problems. Patient tolerance is excellent and, unlike MRI, there are no absolute contraindications to CT. Spatial resolution is high, usually higher than MRI, and contrast resolution between soft tissue and bone is unsurpassed by any other modality. However, despite all the advantages listed above, the application of CT in arthritis imaging still has two fundamental flaws that prevent its universal application. First, CT is constrained in the same way as radiography by its limited soft tissue contrast capability. Second, ionizing radiation is used with increasing dose proportional to size of the body part and requirements for spatial detail. Although this is not a problem with the more distal extremities because the exposure doses are smaller and the tissue more radioresistant, it remains an issue for spine,

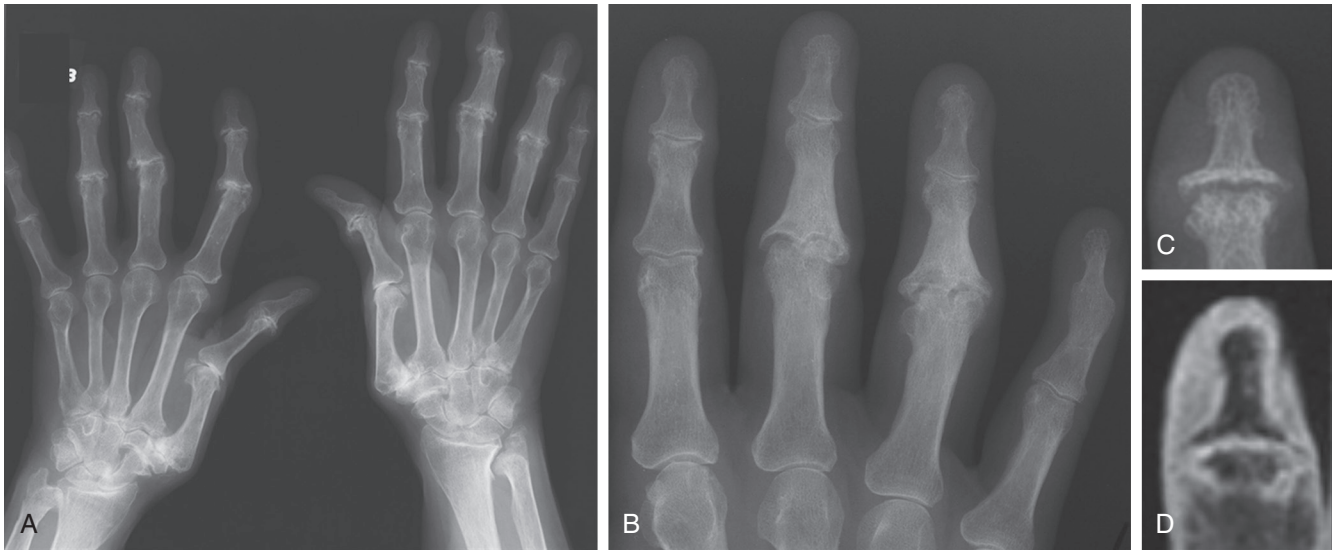

**Figure 58-10 Osteoarthritis of the hand (radiography and MRI). A,** Radiography shows asymmetric cartilage space narrowing at the proximal and distal interphalangeal joints, the first carpometacarpal joints, and the scaphoid-trapezium-trapezoid articulations. Subluxation at the first carpometacarpal joint and secondary hyperextension at the metacarpophalangeal joints are characteristic deformities of osteoarthritis. **B,** "Gull wing" deformities in erosive osteoarthritis: Cartilage loss and bone remodeling at the third and fourth proximal interphalangeal joints produce a gull wing appearance. Radiography **(C)** and coronal MRI **(D)** of distal interphalangeal joint show osteophyte and central erosions/collapse of the bone plate, representing severe osteoarthritis. *(**C** and **D,** Courtesy Dr. Ida Haugen, Oslo, Norway.)*

hip, and shoulder CT. Consequently, in most routine clinical situations, radiography provides sufficient information of a similar nature to CT for clinical decision making and is cheaper than CT and readily available. Ultrasonography is a better and cheaper way to visualize and quantify superficial soft tissue pathology; and MRI offers superior soft tissue contrast and bone marrow imaging. However, the technology continues to evolve, and low-dose CT is becoming more common, with iterative reconstruction techniques which reduce the radiation exposure by approximately 80% and bring the CT dose much closer to conventional radiographic exposure.[51]

## Rheumatoid Arthritis

The exquisite inherent contrast between bone and soft tissue that is afforded by CT makes it a gold standard reference for the detection of bone erosion and, as such, CT is ideally suited to the investigation of erosion in inflammatory arthritides. Modern CT with isotropic voxel acquisition and three-dimensional visualization allows accurate detection and quantification of bone erosion with good intra-observer agreement, whereas radiography is limited by its two-dimensional projection and superimposition of structures. However, CT is very limited in its ability to visualize soft tissue changes and, even with contrast enhancement and complex subtraction techniques, CT is still inferior to MRI and ultrasound for assessment of synovial changes, such as thickening and hyperemia. Furthermore, detection of erosion on CT and MRI shows very good agreement, although CT is slightly more sensitive.[52,53]

### Use in Diagnosis, Monitoring, and Predicting Outcome

CT is not currently used in routine clinical practice for the diagnosis of RA. However, it is potentially useful for diagnosis because CT appears to be the most sensitive technique for detection of erosion,[52,53] and CT of the feet is very simple with a very low radiation dose. CT is used for problem solving in specific cases, such as examination of the cervical spine if MRI is unavailable or contraindicated.

The use of CT for longitudinal assessment of damage progression has potential merit.[53,54] A problem with CT in comparison with MRI or ultrasonography is its inability to demonstrate improvement in soft tissue pathology. No CT data are available for prognostication in RA. The current use of CT in RA is very limited, although its ability to define erosion so clearly offers opportunities for future developments in early diagnosis and clinical trials research.

## Ankylosing Spondylitis/Axial Spondyloarthritis

CT allows for visualization of the same pathologic processes as conventional radiography—erosion, osteoporosis/sclerosis, and new bone formation/ankylosis, with the added benefit of multiplanar imaging free from superimposition of overlying structures (Figure 58-11).

In AS, the pathologic processes start in bone marrow and at sites of enthesis. However, CT has poor ability to detect soft tissue change and the imaging results are usually normal until structural damage is present. CT can detect osteoporosis or osteosclerosis quite well, but these changes are nonspecific. The primary value of CT in AS is its ability to detect and clearly define erosion of bone at any joint or enthesis. New bone formation is also well visualized in the form of syndesmophytes, ligamentous ossification, and periarticular and intra-articular ankylosis, but the use for CT in this regard is limited. CT can show these findings equally well in the axial and peripheral skeleton, but is used primarily in areas where radiographic visualization or interpretation is problematic.

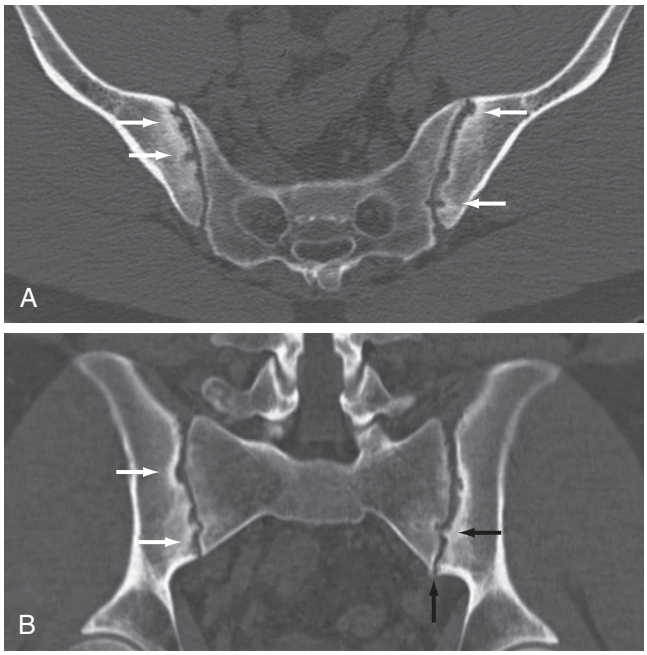

**Figure 58-11 Bone erosion in sacroiliac joints in spondyloarthritis (computed tomography [CT]).** Coronal **(A)** and axial **(B)** CT images of the sacroiliac joints in a patient with spondyloarthritis. Bone erosions *(white arrows)* and mild sclerosis and new bone formation *(black arrows)* are seen.

### Use in Diagnosis, Monitoring, and Predicting Outcome

**Diagnosis.** The diagnosis of AS is primarily based on the radiographic observation of bilateral moderate or unilateral severe sacroiliitis. When good quality radiographs of the sacroiliac joints are normal, or radiographic changes meet diagnostic criteria, there is no role for CT. Early detection of AS is better investigated by MRI and, if clearly defined structural damage is present on radiography, then there is no additional diagnostic utility for CT. However, CT of the sacroiliac joints is much easier to interpret than radiography, which is notoriously subject to poor observer reliability. When the radiographic findings are unclear, CT will usually resolve this uncertainty. Since CT shows bone erosion in exquisite detail, CT may also have a role to play in the further investigation of MRI equivocal findings. It should be noted that classification criteria for AS depend on radiographic findings and more recently MRI but not CT specifically. In the spine, CT is useful in the diagnosis of complications of late disease such as spondylodiskitis or spinal fracture, when patients may be unable to tolerate MRI because of pain or spinal deformity.

**Monitoring Disease Activity and Damage.** CT has no role in monitoring disease activity or damage at this time, because CT cannot show active inflammation and has a relatively high radiation dose. However, recent studies have shown that quantitative measurement of syndesmophyte formation in the spine is reliable and significantly more sensitive to change than assessment by radiography.[55] If these results can be reproduced at lower radiation exposure levels, low-dose CT could have an important future in the monitoring of structural damage progression in the spine.

**Predicting Outcome.** The prognostic value of CT findings of sacroiliitis require further investigation.

## Psoriatic Arthritis

CT is rarely used for the investigation of PsA, and few data are published on this topic. It has been confirmed that, in comparison with radiography, CT is much more sensitive for the detection of small foci of erosion or proliferation of the small bones of the hand.[56,57] CT was highly reliable for the detection of erosion but less so for proliferation, and neither radiography nor CT detected significant change in the bone findings in this short trial. In the peripheral skeleton, it would be expected that the application of CT for PsA would be similar to RA and in the axial skeleton, use of CT would be similar to AS. In both cases, use of CT is limited by the inability to directly visualize inflammation in either bone or soft tissue and, although it has superior ability versus radiography to detect bone erosion and proliferation, in most circumstances the extra radiation dose is not warranted.

### Use in Diagnosis, Monitoring, and Predicting Outcome

CT visualizes bone erosion and bone proliferation, but no systematic studies of specific diagnostic utility or prognostic value have been performed. Because of radiation concerns, CT is not used for disease monitoring in PsA.

## Gout

CT allows for clear visualization of bone erosion, and recent developments in technology offer exciting prospects for crystal imaging. Acute and chronic tophaceous gout is associated with deposition of urate crystals in soft tissues and the development of tophi. Chronic tophi are often partially calcified and all CT scanners are sensitive for the deposition of calcium in soft tissues (see Figure 58-6). The condition frequently involves intraosseous deposition of crystals, and this is much better visualized on CT than radiography.[58] CT shows soft tissue swelling caused by tophi quite well, and because anatomic bone detail is very good on CT, erosions are clearly delineated. Dual-energy CT (DECT) is a new technological development whereby images can be reconstructed based on a two-material decomposition algorithm that can separate calcium from monosodium urate (Figure 58-12).[59] DECT has been used to show that monosodium urate crystals are frequently present in joints affected by radiographic damage in gout, which supports the concept that MSU crystals interact with articular tissues, contributing to the development of structural joint damage.[60]

### Use in Diagnosis, Monitoring, and Predicting Outcome

CT visualizes bone erosions and tophi, but few systematic studies of specific diagnostic utility have been performed. Until recently, CT had no role in the diagnosis of acute gout before the development of bone erosions or tophi because it does not provide imaging of synovitis, tenosynovitis, or osteitis. However, CT scanning with dual-energy acquisition (DECT) is a recent technical development which can accurately detect the presence of monosodium urate with approximately 90% sensitivity and 80% specificity and with excellent reader reliability.[61,62] The sensitivity is less in patients with acute gout, but DECT is quite specific in this

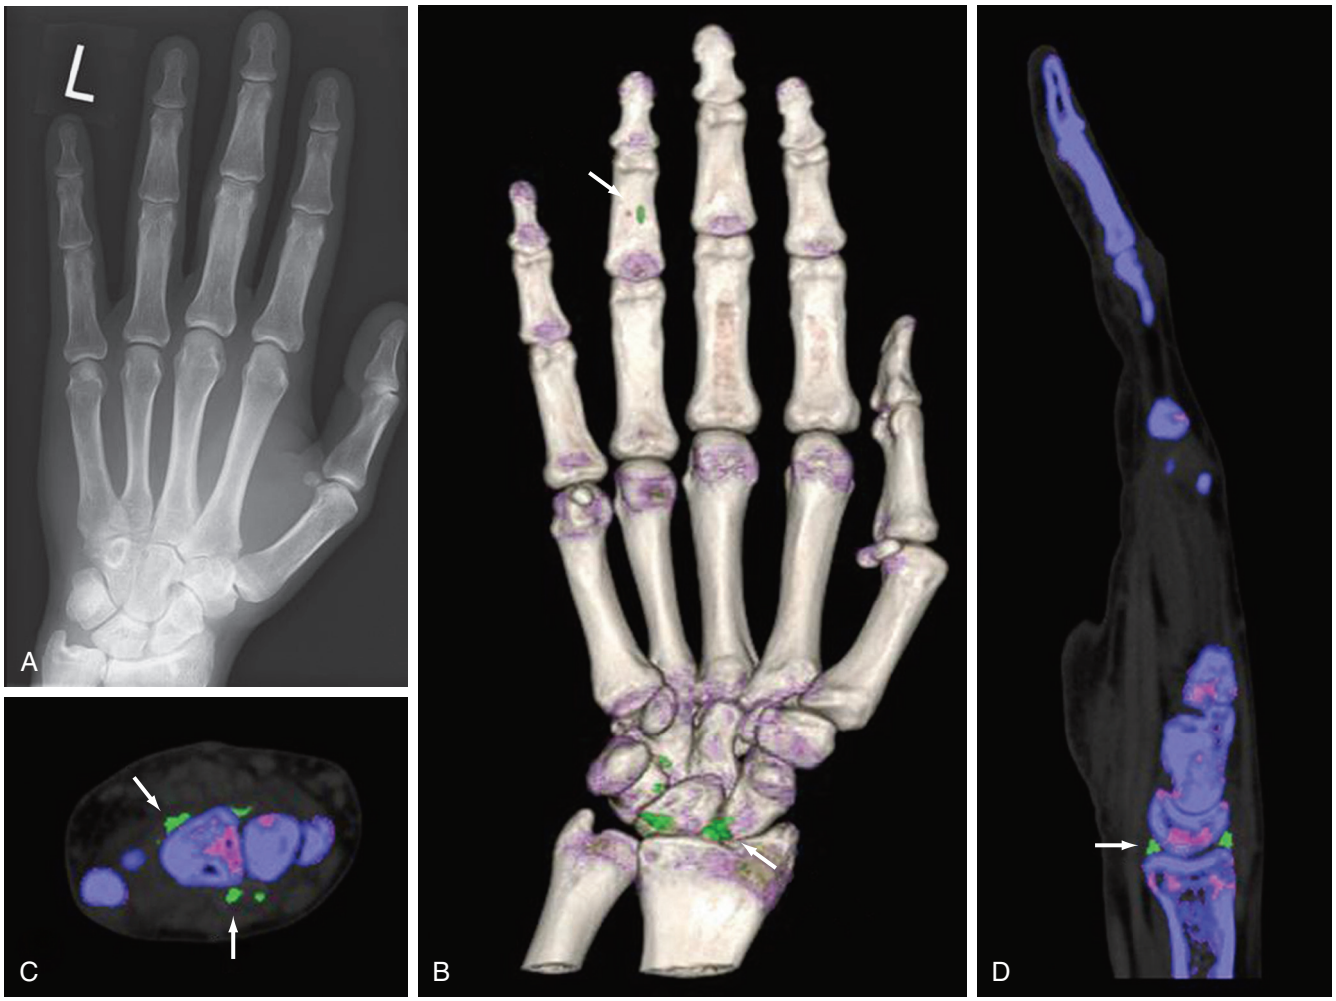

**Figure 58-12 Gout (radiography and dual-energy computed tomography [CT] scan).** Radiography **(A)** and dual-energy CT scans (**B** through **D**) of the left hand and wrist of a 39-year-old male patient with recent onset bilateral pain in hands and wrists. Radiography **(A)** and laboratory investigations were all normal. Dual-energy CT was performed and confirmed the presence of sodium urate crystals in the left wrist and one finger. Left wrist aspiration was attempted but was unsuccessful. The patient responded well to treatment for gout. Imaging findings: After processing of CT data with an algorithm specific for detection of urate crystals (Siemens, Erlangen), the urate crystals are displayed green *(arrows)* on three-dimensional anterior **(B)**, two dimensional transverse **(C)**, and two-dimensional sagittal **(D)** reconstructions.

group, whereas the specificity is less when OA is present. The greatest diagnostic utility of DECT would appear to be in cases of acute gout in small joints, in which the differential diagnosis is septic arthritis and joint fluid is unobtainable, or fluid microscopy fails to demonstrate monosodium urate crystals. Unfortunately, the technology is limited to CT scanners that have dual-source technology, and these scanners are very expensive and not currently widely available.

CT, including DECT, is reliable for monitoring tophus size.[41,63] A bone erosion scoring method has recently been developed.[64] These methods may be useful in trials.

## Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

CT is not used in the management of uncomplicated peripheral CPPD, although calcifications can be visualized. CPPD can involve the cervical spine and cause neck pain. In such patients, CT may visualize CPPD deposition at the craniovertebral junction, often in the transverse ligament of atlas (crowned dens syndrome).[65,66] Calcific deposits may also be found in other periodontoid structures and the ligamenta flava in some patients, in addition to osseous abnormalities of the odontoid process, such as subchondral cysts or erosions. CT may also be used to verify the presence of calcifications at other rare locations (e.g., the temporomandibular joints).[67] In peripheral joints, CT can accurately depict the distribution of CPPD crystals, and has confirmed that, in fact, soft tissue deposition outside cartilaginous structures is common, especially in ligaments and joint capsules.[68]

## Septic Arthritis

CT is rarely used for the investigation of septic arthritis. Acute septic arthritis of large joints is a surgical emergency and although radiography, fluoroscopy, and ultrasound may be useful for either diagnosis or image-guided aspiration, CT is not useful in the peripheral skeleton. In chronic septic arthritis and infectious discitis, CT may be used to investigate complications, particularly osteomyelitis. However,

MRI or a variety of scintigraphic studies are generally preferred.[45] In complex cases in which MRI scanning is problematic, contrast-enhanced CT can be very useful to detect abscess formation in deep soft tissues that are not easily assessed by ultrasound, and CT guidance may be preferred for spine biopsy.

## Osteoarthritis

Even though CT can detect bone changes such as osteophytes more accurately than radiography,[69] overall it offers little additional diagnostic utility in peripheral joints. It generally has poor soft tissue contrast capability, hyaline cartilage cannot be directly visualized, and spatial resolution of bone detail is inferior to radiography. It may be used in specific problem-solving situations in which anatomy is complex and/or poorly visualized on radiography, such as in the lumbar spine facet joints, but this is not usually the case in the peripheral joints. CT is occasionally used to assess the extent of disease, such as in the orthopedic assessment of large joints, where detailed evaluation of bone morphology may be required pre-operatively. CT scanning with intra-articular contrast material (CT arthrography) may be the single most accurate modality for detection of cartilage thinning, fissuring, flaps, or volume[70] (Figure 58-13) and loose intra-articular bodies. This requires both a minimally invasive procedure and radiation exposure and is not widely used. Experimentally it has been shown that CT arthrography can detect changes related to alteration of the glycosaminoglycan (GAG) content of hyaline cartilage[71]) and that it correlates well with gadolinium-enhanced MRI estimates of cartilage damage, but neither modality correlates with arthroscopic findings in early disease.[72] CT arthrography may be used as a problem-solving tool in patients who are not able to undergo MRI.

### Use in Diagnosis, Monitoring, and Predicting Outcome

CT is not currently used in routine clinical practice for the diagnosis of OA, has no role for monitoring disease because it cannot quantify change in the target tissue (cartilage) without an invasive procedure, and no published data are available on the independent prognostic use of CT because good-quality radiography usually provides the same or more information.

# MAGNETIC RESONANCE IMAGING

**KEY POINTS**

**MRI allows sensitive visualization and assessment of peripheral inflammatory and destructive joint and soft tissue involvement in a variety of degenerative and inflammatory rheumatic diseases.**

**MRI is by far the best available method for detecting and monitoring inflammation in the spine and sacroiliac joints in AS and other spondyloarthritides.**

**MRI allows monitoring of inflammatory soft tissue changes (e.g., synovitis, tenosynovitis, and enthesitis) during treatment of patients with peripheral inflammatory joint diseases.**

**Through detection of early inflammatory changes, MRI can contribute to earlier diagnosis of RA and SpA.**

**MRI bone edema is uniquely visualized by MRI, and provides prognostic information in RA, SpA, OA, undifferentiated inflammatory arthritis and, possibly, other rheumatic arthritides**

**The main disadvantages of MRI are costs and lack of availability.**

MRI provides multiplanar tomographic imaging with unprecedented soft tissue contrast, without the use of ionizing radiation, and allows assessment of all the structures involved in musculoskeletal diseases. MRI is more sensitive than clinical examination and radiography for detection of inflammation and damage in inflammatory and degenerative rheumatologic disorders. Disadvantages of MRI include higher costs and lower availability than radiography, longer examination times and restriction to a limited anatomic area per session. It should be remembered, however, that the costs of MRI are only a small fraction of the cost of biologic treatment or of the indirect costs of sick leaves and early retirements.

Preceded by a section on key technical aspects, the characteristics of MRI (with respect to diagnosis, monitoring, and prognostication) and its clinical utility in RA, SpA, PsA, gout, and OA will be described in subsequent text.

## Technical Aspects

T1-weighted (T1w) imaging sequences are characterized by relatively short imaging times, good anatomic detail and the ability to visualize tissues with high perfusion and permeability, including the inflamed synovium, after intravenous contrast (paramagnetic gadolinium [Gd] compounds) injection. Fat and Gd-enhanced tissues have a high signal intensity on T1w images (Figure 58-14). T2-weighted (T2w) images depict both fat and fluid/edematous tissues with a high signal intensity. These are used together with T1w images in the diagnosis of degenerative spine disease. In inflammatory conditions T2w images with fat-saturation (FS) (Figure 58-15) are particularly useful because the signal from fat is suppressed in such sequences. This allows the detection of edematous tissue/fluid located in areas with fatty tissue (e.g., bone marrow edema). FS requires a homogenous field and a high magnetic field strength, not available on low field (<1.0 T) MRI units. The only fat-suppressed sequence possible on low-field MRI, the STIR (short tau inversion recovery) technique, based on relaxation time differences, can provide information on bone marrow edema,[73] even though with less detail.

Whereas MRI examination of axial joints require whole-body MRI units, MRI of the peripheral joints can be performed with whole-body MRI-units or dedicated extremity MRI-units (E-MRI). E-MRI increases the potential for widespread rheumatologic use, through markedly lower costs, more comfortable patient positioning, and elimination of claustrophobia.

Some E-MRI units may provide information on synovitis and bone destructions not markedly inferior to what is obtained by standard sequences on high-field units,[73,74] but the performance of different machines varies. For some

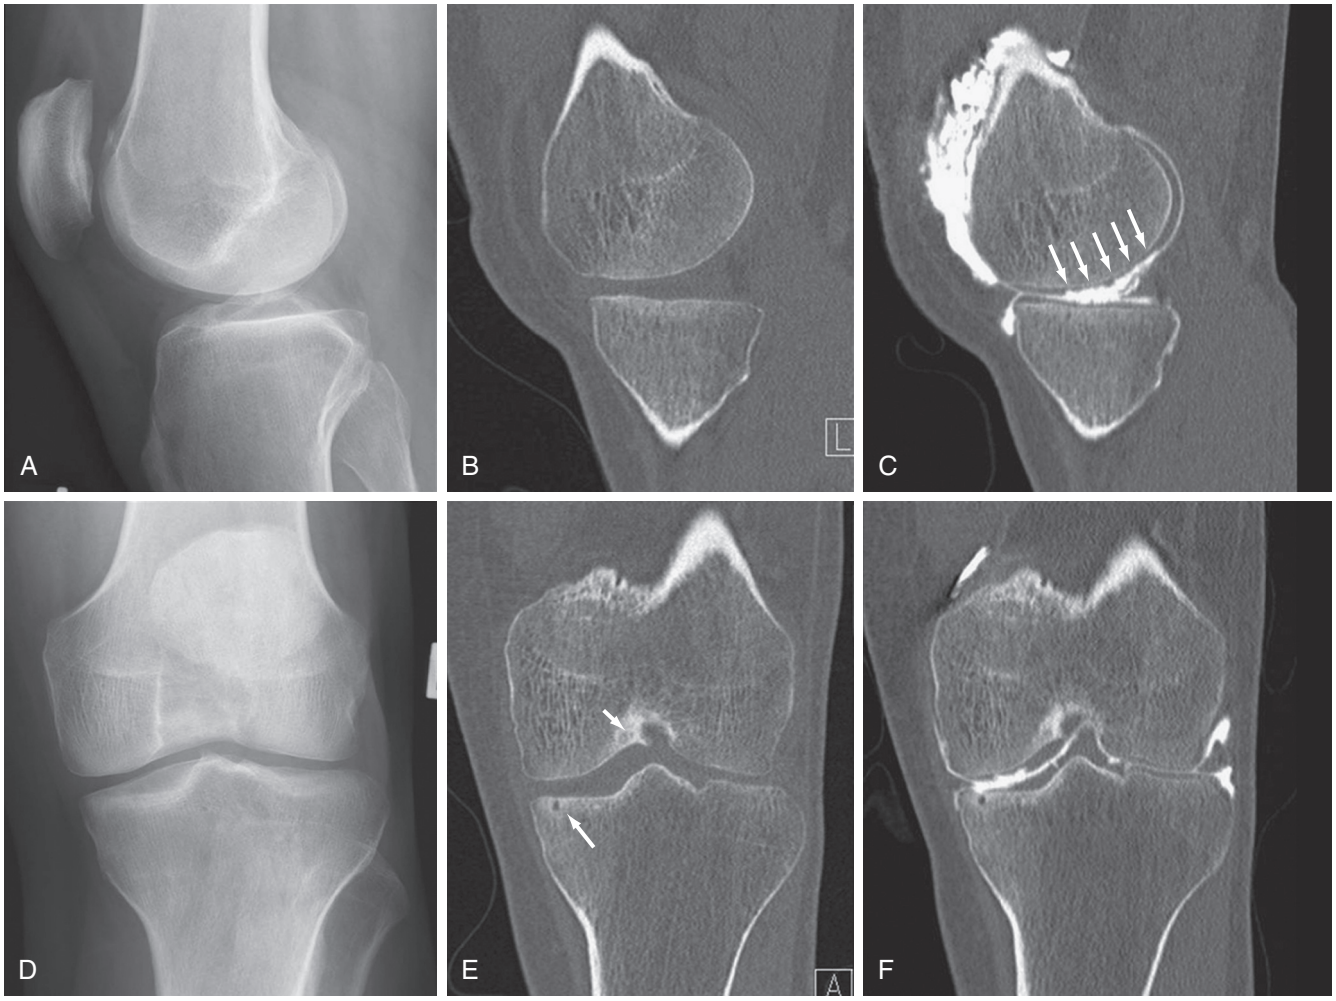

**Figure 58-13** Radiography, computed tomography (CT), and CT arthrogram of the knee in a 46-year-old male patient with unexplained pain and locking. Initial radiographs (**A** and **D**) appear near normal with preserved joint space, a tiny osteophyte arising from the medial tibial spine, and no other definite abnormality. CT scan with sagittal **(B)** and coronal **(E)** reconstructions confirms the presence of osteophytosis *(short arrow)* and a small subchondral cyst *(long arrow)* but show no definite chondral changes. CT arthrogram with sagittal reconstruction **(C)** demonstrates several focal hyaline cartilage thinning *(arrows)* and a meniscal tear. On the coronal reconstruction **(F)**, the tibial subchondral cyst is associated with complete loss of overlying hyaline cartilage.

units smaller field of view, longer imaging times, and lack of certain imaging techniques (particularly FS at low field) should be considered.[75]

The majority of MRI studies of the sacroiliac joint have used only one imaging plane (semi-coronal, i.e., parallel with the axis of the sacral bone). A supplementary T1w FS sequence may improve the evaluation of erosions,[76] and sequences designed for cartilage evaluation (e.g., 3D gradient echo sequences), may also be added.[77] To be maximally sensitive for changes in the ligamentous portion of the sacroiliac joints, imaging in the semiaxial plane is required.[76] This sequence may therefore be recommended when MRI is used for diagnostic purposes, although it is probably not essential when used as an outcome measure in trials. Although MRI on some indications (e.g., suspected disk herniation) should include axial images, MRI of the spine in SpA generally only involves sagittal images, but these should extend sufficiently lateral to include the frequently involved facet, costovertebral, and costotransversal joints.[78] Bone marrow abnormalities in both the sacroiliac joints and spine are detected almost equally well with the STIR and contrast-enhanced T1w FS sequences in patients with SpA, thus contrast injection is generally not needed.[79,80] In contrast, contrast injection increases the sensitivity for synovitis in peripheral joints.[81] To evaluate structural (sometimes referred to as *chronic*) changes, such as bone erosion, new bone formation, and fat infiltrations, T1-weighted images are mandatory. A supplementary T1w FS sequence may improve the evaluation of erosions.[76] In peripheral as well as axial joints, specific sequences designed for optimal cartilage evaluation can be applied (e.g., 3D gradient echo sequences).[77]

New MRI techniques are being developed all the time, and a variety of sequences are now available for the detection of increased water content in bone marrow such as occurs with inflammation—so-called *bone marrow edema* (BME). These include T2 with fat-saturation (T2 FS), T2 with water-excitation (WE), STIR, hybrid sequences, and chemical shift–based fat-water separation with the Dixon technique.[82] All of these sequences have advantages and

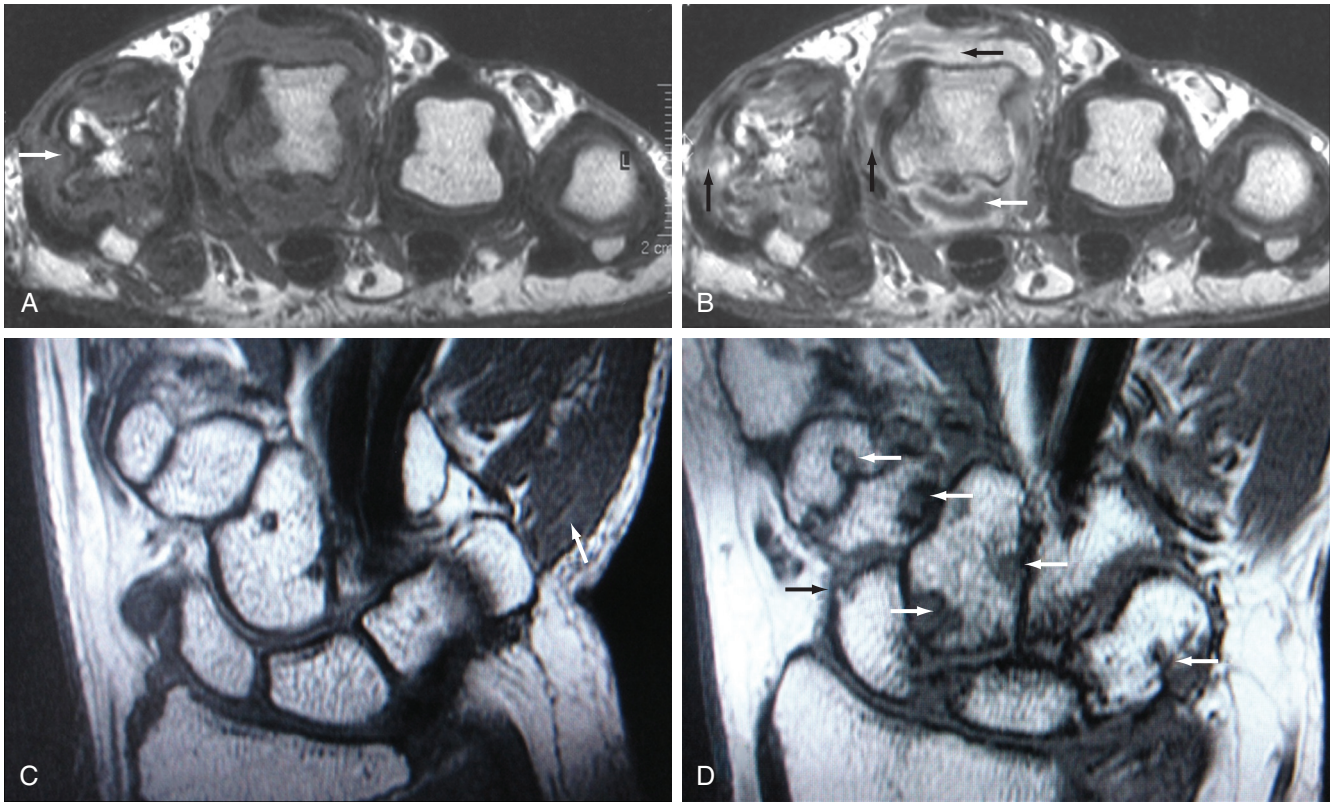

**Figure 58-14 Rheumatoid arthritis (MRI).** Axial T1-weighted precontrast **(A)** and postcontrast **(B)** MRI of the second *(left)* through fifth *(right)* fingers at the level of the metacarpophalangeal joints in a patient with rheumatoid arthritis (RA). Synovitis (*black arrows* in **B**), joint effusion (*white arrow* in **B**), and severe bone erosion (*arrow* in **A**) are seen. Coronal T1-weighted precontrast MRI of the wrist **(C)** in another patient with RA shows no bone erosions. Similar images 1 year later **(D)** show severe erosive progression (bone erosions marked by *arrows*).

disadvantages, and at this time it would appear that none of them consistently alters the diagnostic properties of MRI for the detection of BME. Most centers continue to use the more traditional T2 FS or STIR sequences because almost all MRI scanners can perform these two sequences, they are generally reliable, and fairly consistent across different manufacturers and magnetic field strengths.

The potential for molecular imaging with MRI is an exhilarating prospect for arthritis research and the future of clinical practice. Most of the work in this field is still at an experimental stage, but numerous techniques are under development for evaluation of the chemical and biophysical structure of musculoskeletal tissues, and articular cartilage in particular. Many publications now attest to the capabilities of T2 or T2* relaxation time mapping,[83,84] delayed gadolinium–enhanced MRI of cartilage (dGEMRIC).[85,86] T1ρ imaging (T1rho–T1 properties in the rotating frame of reference),[87,88] glycosaminoglycan chemical exchange saturation transfer (gagCEST),[89,90] diffusion tensor imaging (DTI),[91,92] and sodium MRI.[93,94] All of these MRI developments are highly technical, require dedicated software and/or hardware, and are very challenging to perform consistently. Several have been proposed for use in clinical practice, but none have established unequivocal utility beyond a standard set of high-quality sequences. Of all these new developments, DTI may have the most promise (Figure 58-16). It is a noninvasive technique in which the signal produced is dependent on water movement. One component of the DTI produces a result that is primarily dependent on the speed of water movement independent of direction—apparent diffusion coefficient (ADC)—creating an ADC map, whereas another component of the DTI, fractional anisotropy (FA), produces a result that is primarily dependent on the direction of water movement and is much less dependent on speed, creating an FA map. This technique is interesting because in cartilage the ADC is affected mostly by glycosaminoglycan concentration and distribution, whereas the FA is heavily dependent on the orientation and degree of organization of the collagen fibers. The DTI sequence would therefore seem to be capable of supplying all, or most, of the information available from all the other technologies combined.

Whole-body MRI is another technique in development. It allows imaging of the entire body in one examination, and has been introduced as a potential method for simultaneous assessment of peripheral and axial joints and entheses in both RA (Figure 58-17) and SpA/PsA (Figure 58-18).[95,96] The method still needs improved image quality and more validation, and it is not yet ready for clinical use. However, the method seems extremely promising, especially in PsA, because of the diverse manifestations of the disease.[96-98]

MRI is very safe. It involves no ionizing radiation and thereby no associated increased risk of malignancies. Adverse reactions to gadolinium-based contrast media (GBCM) are infrequent. In 2006 it became clear that that there is a link between exposure to some less stable GBCM and the development of nephrogenic systemic fibrosis (NSF) in patients with reduced renal function or on

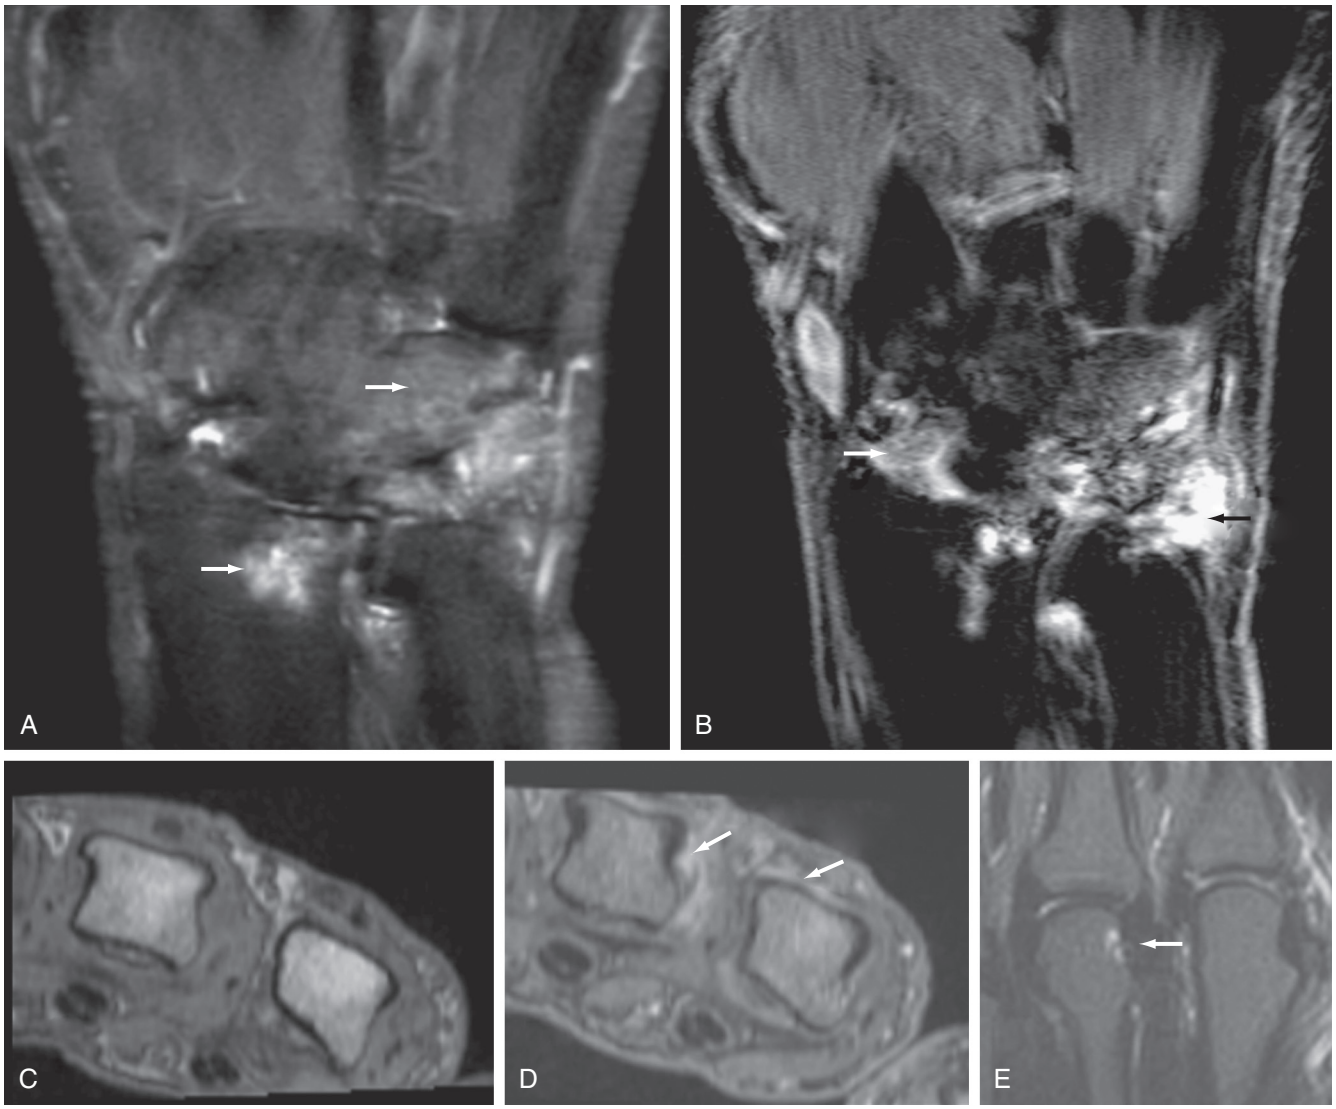

**Figure 58-15 Rheumatoid arthritis (RA) in clinical remission (MRI) and undifferentiated arthritis (MRI). A** and **B**, Patient with RA in clinical remission. Despite clinical remission, coronal short tau inversion recovery (STIR) **(A)** and postcontrast T1-weighted fat-suppressed **(B)** MRI show marked bone marrow edema (osteitis, *arrows* in **A**) and synovitis (*arrows* in **B**). **C** through **E,** Patient with undifferentiated arthritis. Axial T1-weighted precontrast **(C)** and postcontrast **(D)** T1-weighted MRI views show synovitis in second and third metacarpophalangeal joints *(arrows)*, whereas the STIR sequence **(E)** shows bone edema *(arrow)*. Radiography was normal. One year later the patient had developed RA, according to the American College of Rheumatology 1987 criteria. *(Courtesy Dr. Anne Duer-Jensen, Glostrup, Denmark.)*

dialysis.[99,100] NSF is a rare fibrosing condition which causes thickening and hardening of the skin, and sometimes involves organs such as liver, lungs, and heart.[101,102] In 2007, the European Medicines Agency (EMA) contraindicated the use of the least stable GBCM (gadoversetamide, gadodiamide, and gadopentetate) in patients with severely reduced renal function (glomerular filtration rate [GFR] <30 mL/min/1.73m$^2$) or on dialysis and required that they be used with caution in patients with moderately reduced renal function (GFR, 30 to 60 mL/min/1.73m$^2$). In 2010 the U.S. Food and Drug Administration (FDA) also contraindicated the three agents.[103] Since 2009 no new cases have been published, and NSF may have been eliminated by no longer using the less stable gadolinium-based contrast agents in patients with reduced renal function, or, in some countries, by not using the less stable agents at all.[104]

The European Society of Urogenital Radiology (ESUR) guidelines recommend that one should never deny any patient a well-indicated, enhanced MRI. Furthermore, one should use the lowest diagnostic dose of GBCM and agents with the highest stability (lowest risk of NSF) (e.g., gadoterate meglumine, gadoteridol, and gadobutrol).[105] The pharmacokinetics and diagnostic performance of these agents are similar to those contraindicated in patients with poor renal function. Therefore, it seems logical to use the low-risk agents in every patient, independent of renal function.

## Rheumatoid Arthritis

The majority of MRI studies in patients with RA have investigated knee, wrist, and finger joints. Although the

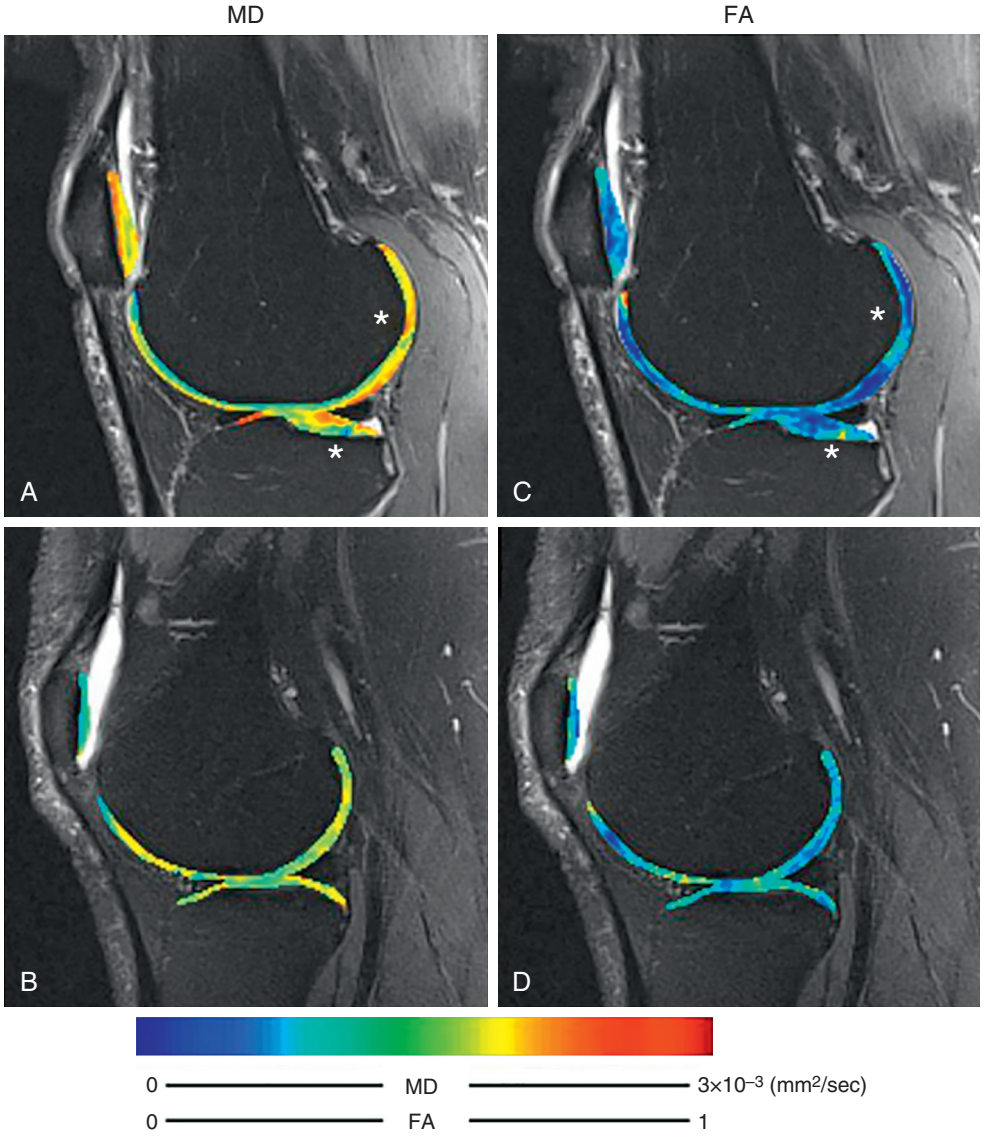

**Figure 58-16 Diffusion tensor imaging (DTI) of hyaline cartilage: sagittal MRI of the knee performed at 3 tesla by using a RAISED (radial spin echo diffusion tensor imaging) sequence.** Diffusion tensor imaging is an MRI technique that displays intensity of signal, often by using color scales, to represent specific properties of water within a tissue. It has two primary components that relate to water movement at the microscopic level. Mean diffusivity (MD) (**A** and **C**) is the mean of the apparent diffusion coefficients (ADC) and is representative of the degree (speed) of water movement (brighter = faster). Anisotropy is the property of being directionally dependent and fractional anisotropy (FA) (**B** and **D**) records the degree to which the direction of water movement in a tissue is constrained by the microscopic architecture of the tissue (brighter = more directionally dependent and less random). Subject 1 (**A** and **B**) is a patient with Kellgren Lawrence grade 2 osteoarthritis (OA). Some of the water in the hyaline cartilage (adjacent to *asterisks*) is less tightly bound, and thus the MD of the cartilage appears more in the red end of the scale in comparison with subject B, who is a healthy volunteer. Damage to the cartilage in early OA results in proteoglycan loss, and the water in the cartilage is less tightly bound and thus it can move faster. The structure of the collagen network may also be damaged in early OA, and the FA map in subject 1 shows that some of the cartilage has less fractional anisotropy and appears as a darker blue (adjacent to *asterisks*) compared with the healthy volunteer (subject 2) (**C** and **D**). While the highly organized collagen network starts to break down, the motion of the water becomes more random and less directionally dependent. By using these measurements, DTI has the unique capacity to separately detect damage in hyaline cartilage to both collagen and proteoglycan. *(Courtesy Dr. José Raya, New York, New York.)*

knee is an excellent model for methodological studies, the clinical value of MRI is mainly dependent on its power to evaluate wrists, hands and feet, which is also the primary focus of this section. Reports on other peripheral joints are few and not essentially different. Definitions of key pathologies in RA and PsA are provided in Table 58-3.

MRI allows for assessment of all the structures involved in RA ( i.e., synovial membrane, intra- and extra-articular fluid collections, cartilage, bone, ligaments, tendons, and tendon sheaths; see Figure 58-14). MRI, histopathologic, and mini-arthroscopic signs of synovial inflammation are closely correlated.[106,107] MRI bone marrow edema (see Figure 58-14) represents inflammatory infiltrates in the bone marrow (i.e., osteitis, as demonstrated by comparison with histologic samples obtained at surgery in patients with RA).[108,109] Whereas erosions reflect bone damage that has already occurred, bone marrow edema appears to represent the link between joint inflammation and bone destruction.

**Figure 58-17 Whole-body MRI of patient with rheumatoid arthritis (RA) and osteoarthritis and degenerative disk disease.** Short tau inversion recovery MRI of the shoulder girdle **(A)**, the right hand **(B)**, the hips **(C)**, the left hand **(D)**, the right **(E)** and left **(F)** knee, the right **(G)** and left **(H)** ankle and midfoot, the right **(I)** and left **(J)** foot, and the upper **(K)** and lower **(L)** spine. MR images show mild inflammation of the right acromioclavicular joint (*arrow* in **A**); inflammation of the wrist, first carpometacarpal joints, and several metacarpophalangeal and interphalangeal joints (*arrows* in **B** and **D**); a Baker's cyst in the right knee (*arrow* in **E**); inflammation in the right medial tarsometatarsal joint (*arrow* in **G**); tenosynovitis of the left flexor hallucis longus tendon (*arrows* in **H**); inflammation in the right first metatarsophalangeal joint (*arrow* in **I**); and several disk protrusions (*arrows* in **K** and **L**), but no spinal inflammation. The images were obtained in less than 45 minutes on a 3 Tesla MRI unit.

A high level of agreement for detection of bone erosions in wrists of patients with RA and MCP joints (concordance at 77% to 90% of sites) between MRI and CT, which is the gold standard reference for detection of bony destruction, documents that MRI erosions represent true bone damage.[52,110]

In the cervical spine, the primary imaging modality is CR, but MRI can provide detailed information on bone and soft tissue abnormalities, which can be a valuable supplement to radiographic evaluation[111-117] (see Figure 58-2C). MRI is able to directly visualize the pannus tissue (e.g., around the odontoid process). Cord compression on MRI seems a better predictor for deterioration than initial clinical and plain radiographic features, evidence that MRI is the imaging method of choice for evaluation of spinal cord affection in RA.[118]

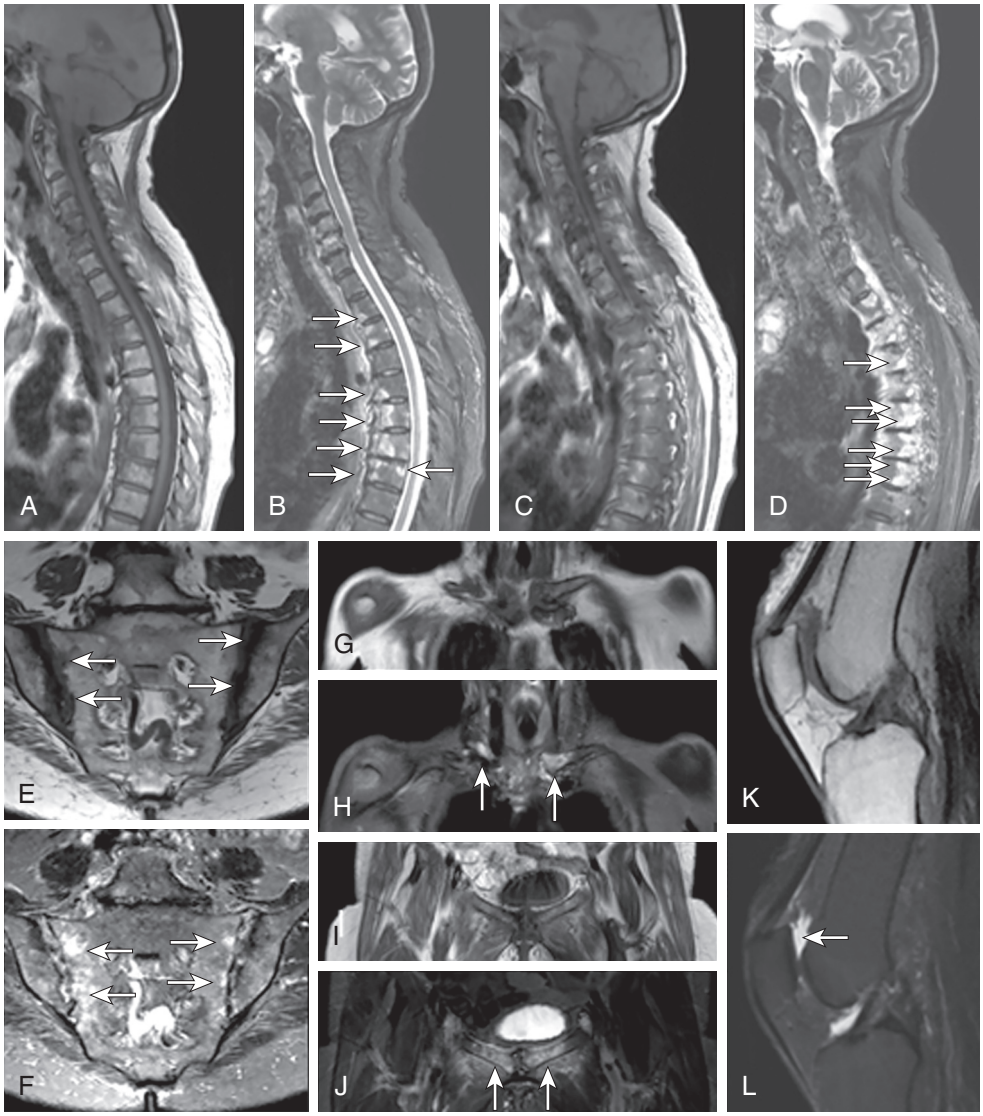

**Figure 58-18 Whole-body MRI of patient with spondyloarthritis (SpA).** T1-weighted (**A**, **C**, and every second image thereafter) and short tau inversion recovery (**B**, **D**, and every second image thereafter) at before (**A** through **L**) and 4 months after (**M** through **Y**) initiation of anti-TNF therapy. Before anti-TNF initiation, MR images of the central (**A** and **B**) and lateral (**C** and **D**) cervical and thoracic spine shows anterior corner inflammatory lesions (*arrows* in **B**) and inflammation in the pedicles and costovertebral joints (*arrows* in **D**). MRI of the sacroiliac joints (**E** and **F**), shoulder girdle (**G** and **H**), anterior pelvic girdle (**I** and **J**) and right knee (**K** and **L**), shows severe sacroiliac bone erosion (*arrows* in **E**), active sacroiliitis (*arrows* in **F**), sternoclavicular joint inflammation (*arrows* in **H**) and inflammation of the pubic symphysis (*arrows* in **J**), and mild knee joint effusion/synovitis (*arrow* in **L**).

### Use in Diagnosis, Monitoring, and Predicting Outcome

**Diagnosis.** Two large follow-up studies of undifferentiated arthritis have documented an independent predictive value of MRI in the diagnosis of RA.[119,120] Presence of bone edema (see Figure 58-15) had a positive predictive value of 86.1% for subsequent development of RA,[119] and a prediction model, including clinical hand arthritis, morning stiffness, positive RF, and MRI bone edema score in MTP and wrist joints correctly identified the development of RA or non-RA in 82% of patients.[120]

In the recent ACR/EULAR 2010 criteria for RA,[6] classification as definite RA is based on the presence of definite clinical synovitis (swelling at clinical examination in one or more joints, absence of an alternative diagnosis that better explains the synovitis, and achievement of a total score of 6 or more (of a possible 10) from the individual scores in four domains. In the joint involvement domain, which can provide as many as 5 of the 6 points needed for an RA diagnosis, MRI and ultrasound synovitis count. In other words, MRI and ultrasonography can be used to determine the joint involvement.[6,121,122]

**Monitoring Disease Activity and Structural Damage.** To be valuable for monitoring joint inflammation and destruction, a method must be reproducible and sensitive to change. MRI allows quantitative (volume or, for synovitis, early contrast enhancement after intravenous contrast injection) as well as less detailed (qualitative: presence/absence; semiquantitative: scoring) evaluation of synovitis, bone edema, and bone erosions. In observational and randomized clinical trials, semiquantitative scoring by the Outcome Measures in Rheumatology (OMERACT) RA

**Figure 58-18, cont'd** After 4 months of anti-TNF therapy, the corresponding images show almost inflammatory activity in the spine (almost absent corner inflammatory lesions in **N**; less but still present costovertebral inflammation in **P**); and the sacroiliac joint (only minimal bone marrow edema in **R**). The inflammation in the sternoclavicular joints (*arrows* in **T**) and pubic symphysis (*arrows* in **V**) is by and large unchanged and the amount of knee joint effusion/synovitis is somewhat increase (*arrows* in **Y**). The images were obtained in less than 45 minutes on a 3 Tesla MRI unit.

MRI (RAMRIS) scoring system has been the most frequently used system. It involves semiquantitative assessment of synovitis, bone erosions, and bone edema in the hands and wrists of patients with RA, based on consensus MRI definitions of important joint pathologies and a core set of basic MRI sequences.[123] The OMERACT erosion scores are closely correlated with erosion volumes estimated by MRI and CT. Good intra- and inter-reader reliability and a high sensitivity to change has been reported, demonstrating that the OMERACT RAMRIS system, after proper training and calibration of readers, is suitable for monitoring joint inflammation and destruction in patients with RA.[124] A EULAR-OMERACT RA MRI reference image atlas has been developed, providing an easy-to-use tool for standardized RAMRIS scoring of MR-images for RA activity and damage by comparison with standard reference images.[125] An MRI joint space narrowing scoring system to be used to assess cartilage damage as an adjunct to the RAMRIS system, has subsequently been developed and validated.[126,127]

MRI allows more sensitive monitoring of inflammation[128] and bone erosion (see Figure 58-14) [129-131] than clinical and radiographic assessments. A large study of 318 methotrexate-naïve patients demonstrated that inhibition of erosive progression by biologic therapy compared with placebo can be demonstrated by MRI by using half of the patients and half of the follow-up time as by radiography.[31] Several randomized controlled trials have documented the superior ability of MRI to discriminate the ability of different therapies to inhibit progressive structural bone and cartilage damage.[132-134]

**Predicting Outcome.** Several studies have demonstrated a predictive value of MRI pathology in wrist and/or MCP joints to radiographic progression. In particular, bone

[1]OMERACT (Outcome Measures in Rheumatology) MRI in inflammatory arthritis task force recommendations for MRI definitions of important pathologies in rheumatoid arthritis and peripheral psoriatic arthritis.[123,172]

[2]Canada-Denmark MRI Working Group and MORPHO group recommendations for MRI definitions of important pathologies in spine and sacroiliac joints in axial spondyloarthritis.[148,149,151]

marrow edema (see Figure 58-14) has been established as a strong independent predictor of subsequent radiographic progression in early-stage RA.[135-136] Regression analyses in 3-year and 5-year follow-up in the two respective cohorts have documented that bone edema found by MRI is a strong predictor of long-term radiographic progression.[137-138] Recent clinical trial data have confirmed this predictive value, and have also confirmed that early treatment-induced changes in bone marrow edema and synovitis predict the rate of future radiographic progression.[139] Small studies have indicated a relationship of baseline MRI findings with long-term functional disability[140] and tendon rupture at 6 years.[141]

Another issue of high clinical importance is whether MRI is useful to predict the disease course in patients in clinical remission (see Figure 58-15). MRI and ultrasound findings of synovitis are found frequently in patients in clinical remission,[142,143] and several studies have reported that baseline MRI and/or ultrasound findings of inflammation are significantly related to subsequent progressive structural damage.[144-146] These studies encourage further exploration of MRI and ultrasound for predicting the disease course and for evaluating disease status, including defining remission.

## Ankylosing Spondylitis/Axial Spondyloarthritis

MRI allows direct visualization of the abnormalities in peripheral and axial joints and entheses that occur in AS,

PsA, and other forms of SpA. AS, which is thought to be the most common and most typical form of SpA, is dominated by axial disease manifestations in the spine and sacroiliac joints. In accordance with this, this section will mainly focus on the axial manifestations, whereas the PsA section below will deal with peripheral manifestations.

Through its ability to detect inflammatory changes in bone and soft tissues, MRI is the most sensitive imaging modality for recognizing early spine and sacroiliac joint changes in AS.[28,32,147] MRI findings indicating active disease in the sacroiliac joints (sacroiliitis) include juxta-articular bone marrow edema and enhancement of the bone marrow and the joint space after contrast medium administration, while visible chronic changes include bone erosions, sclerosis, periarticular fatty tissue accumulation, bone spurs and ankylosis (Figure 58-19). Typical lesions of the spine, which indicate active disease, are spondylitis, spondylodiskitis (Figure 58-20), and arthritis of the facet, costovertebral, and costotransverse joints (Figure 58-21).[28,147,148] Chronic changes, such as bone erosions, focal fat infiltration, bone spurs and/or ankylosis (see Figure 58-21),[149] frequently occur. Enthesitis is also common, and may affect the interspinal and supraspinal ligaments and the interosseous ligaments in the retroarticular space of the sacroiliac joints. Some patients also have disease manifestations in peripheral joints and entheses, and these can be visualized by MRI.[28,147] Definitions of key pathologies in SpA are provided in Table 58-3. Table 58-2 lists the recent EULAR recommendations for use of imaging in the diagnosis and management of SpA.[32]

### Use in Diagnosis, Monitoring, and Predicting Outcome

**Diagnosis.** The introduction of MRI has resulted in a major improvement in the evaluation and management of patients with SpA. Diagnosis was previously dependent on the presence of bilateral moderate or unilateral severe radiographic sacroiliitis, as part of the modified New York criteria for AS.[25] This frequently delayed the diagnosis by 7 to 10 years.[29] Now, through the recent ASAS (Assessment of Spondyloarthritis) classification criteria for axial SpA, MRI forms an integral part because patients with active sacroiliitis on MRI (Figure 58-22) plus one clinical feature (e.g., psoriasis, enthesitis, or uveitis [see Reference 30 for complete list]), should be classified with axial SpA.[30] A consensus-based definition of the requirements to constitute active sacroiliitis (i.e., fulfill the MRI criterion of the ASAS criteria: a positive MRI) has been formulated: bone marrow

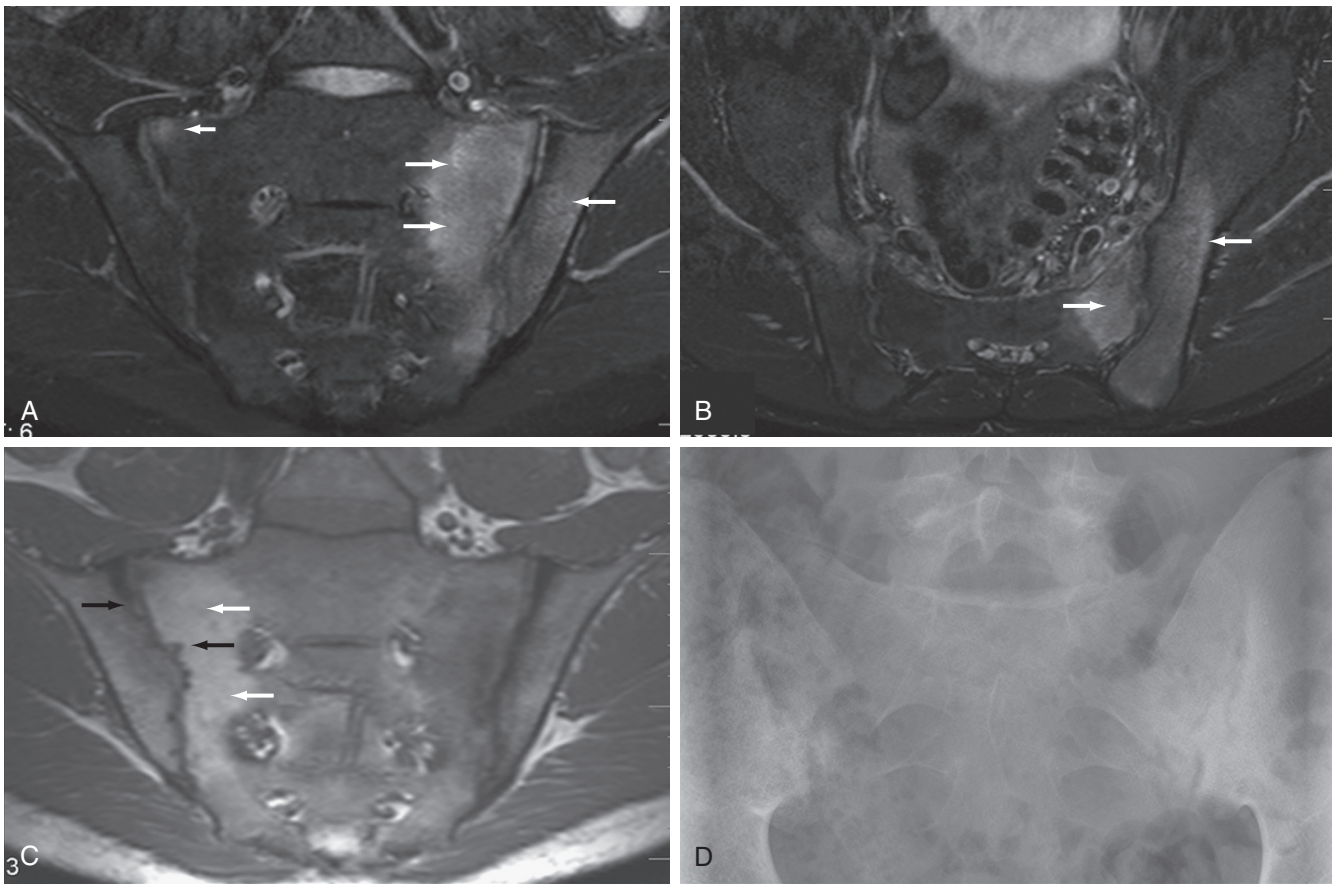

**Figure 58-19 Sacroiliitis in spondyloarthritis (MRI and radiography).** MRI (**A** through **C**) and radiography (**D**) of the sacroiliac joints of 26-year-old male with inflammatory back pain for 4 years. Semicoronal **(A)** and semiaxial **(B)** short tau inversion recovery images show massive iliac and sacral bone edema around the left sacroiliac joint (i.e., demonstrate severe active sacroiliitis) (*long arrows* in **A** and **B**). Inflammation (sacroiliitis) is also present in the right sacroiliac joint (*short arrow* in **A**). T1-weighted semicoronal image shows fat infiltration *(white arrows* in **C**) and bone erosion (*black arrows* in **C**). Anteroposterior radiograph **(D)** shows bilateral mild sclerosis on the iliac side, and bilaterally the articular surface is less well defined than normal, consistent with erosion. However, this feature is exaggerated by overlying bowel gas. *(Courtesy Dr. Susanne Juhl Pedersen, Glostrup, Denmark.)*

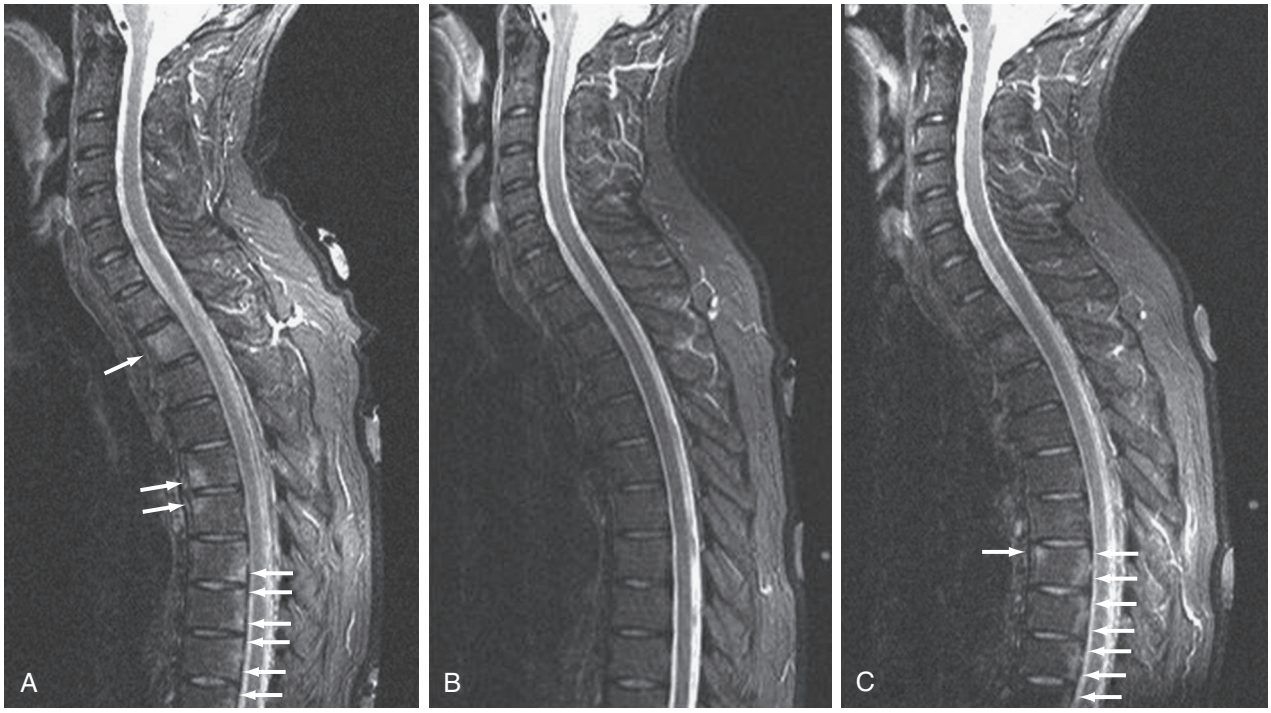

**Figure 58-20 Spine inflammation in ankylosing spondylitis (MRI).** A 43-year-old man with HLA-B27 positive ankylosing spondylitis with deteriorating symptoms, including inflammatory back pain, had an MRI scan before starting biologic therapy. Baseline sagittal short tau inversion recovery (STIR) MRI **(A)** shows diffuse increased signal (edema) in the T2 vertebral body and multiple foci of corner inflammation anteriorly at T5 and 6, and posteriorly at T7, T8, T9 and T10 *(arrows)*. Other images confirmed extensive active inflammation in the spine. The patient responded very well, and after 6 months of therapy, a repeat STIR MRI **(B)** showed complete resolution of bone marrow inflammation. Subsequently, the patient experienced recurrence of symptoms, and a third MRI **(C)** was performed (2 months after anti-TNF therapy was stopped). This MRI shows no edema at T5-T6, a conspicuous new lesion anteriorly at T7, and recurrent inflammation posteriorly in the lower thoracic spine *(arrows)*.

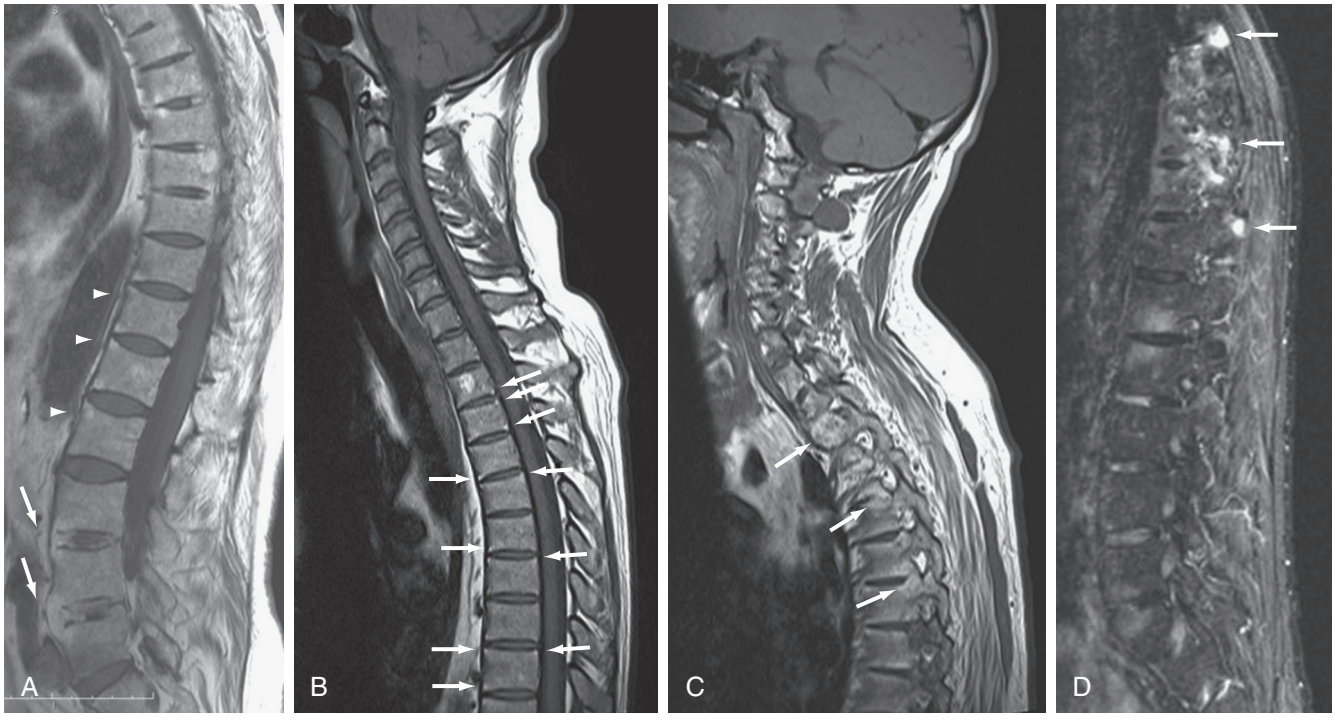

**Figure 58-21 The spine in ankylosing spondylitis (MRI). A** through **C,** T1-weighted sagittal MRI of three different patients with AS shows different structural lesions. **A,** Fat infiltration *(arrowheads)* in the bone marrow of several lumbar vertebral corners and anterior fusion *(arrows)* at L3-L4 and L4-L5. **B**, Fatty infiltration *(arrows)* in the bone marrow of multiple vertebral corners in the cervical spine, indicative of the diagnosis of spondyloarthritis. **C,** Extensive increased marrow fat signal *(arrows)* crossing the costovertebral joints (thoracic ankylosis) is seen, as are changes in several facet joints and other posterior elements. **D,** Sagittal short tau inversion recovery MRI shows intense inflammation in the bone marrow of the transverse processes and facet joints of the lower thoracic spine *(arrows)*, as well as less intense inflammation in several discovertebral joints.

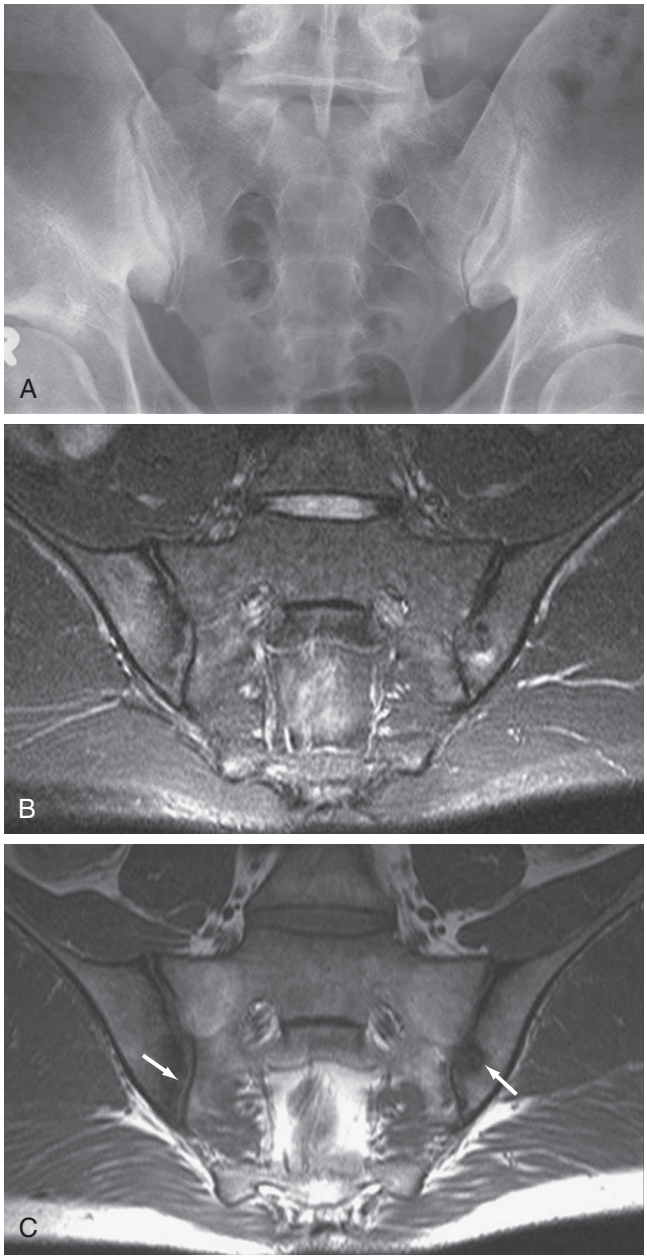

**Figure 58-22 Inflammatory back pain (radiography and MRI).** A 31-year-old man with inflammatory back pain. **A,** Radiography of the sacroiliac joints demonstrates only very subtle findings with possible sclerosis on the iliac side of the right sacroiliac joint and subtle spur formation at the inferior margin. **B** and **C,** MRI at the same time shows obvious findings of spondyloarthritis with mild bilateral iliac inflammation on short tau inversion recovery **(B)** and multiple findings on T1-weighted images **(C)**, including sclerosis most prominent on the right side and subchondral erosion *(arrows)*, which are very small on the right side and obvious on the left side.

edema located in two or more sites and/or in two or more slices.[150]

Subsequent data demonstrate that incorporating structural damage lesions (erosions) into the criteria would improve the diagnostic utility of MRI.[151-154] In contrast, sacroiliac joint fat lesions and/or spine lesions have not been found to improve the diagnostic utility of MRI.[155,156] An update of the ASAS MRI criterion has not yet been published.

**Monitoring Disease Activity and Damage.** MRI can provide objective evidence of currently active inflammation in patients with SpA (see Figure 58-20).[28,147] Until the introduction of MRI, disease activity assessment was restricted to patient-reported outcomes, such as the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) and Functional Index (BASFI), because disease activity could not be assessed in a sensitive manner by biochemical (mainly C-reactive protein [CRP]) or physical evaluation.

Several systems for assessment of disease activity in the sacroiliac joints and in the spine have been proposed (see Reference 157 for details). Reproducible and responsive methods are available.[158] The sensitivity to change and discriminatory ability of the three most used spine scoring systems (The Ankylosing Spondylitis spine Magnetic Resonance Imaging-activity [ASspiMRI-a] score, the Berlin modification of the ASspiMRI-a score, and the Spondyloarthritis Research Consortium of Canada (SPARCC) scoring system[159-161] have been demonstrated in clinical trials, and they have been tested against each other by the ASAS/OMERACT MRI in AS group.[158] All methods were feasible, reliable, sensitive to change, and discriminating. The SPARCC method had the highest sensitivity to change as judged by Guyatt's effect size, and the highest reliability as judged by the inter-reader intra-class correlation coefficient (ICC).[158] Separate MRI assessment of different inflammatory and structural findings at distinct anatomic locations in each discovertebral unit will allow for study of the temporal and spatial course of the disease development.[148,149] MRI is much less established for the assessment of structural changes (often referred to as *chronic changes*) than inflammatory changes. Because MRI provides otherwise inaccessible information on inflammatory activity, an equal effectiveness of MRI and radiography in assessing structural damage is a step forward because radiography and the ensuing need for two examinations and exposure to ionizing radiation could then be avoided. Scoring methods assess erosions, sclerosis, fat deposition, and/or bone bridges separately or as a global score.[149,159,162] The validation of methods for damage assessment is limited and their value is not yet clarified.

**Predicting Outcome.** Three spine studies have documented an association between the presence of bone marrow edema at the anterior corners of the vertebrae on MRI and subsequent development of syndesmophytes on radiography after 2 years of follow-up. Presence as opposed to absence of MRI anterior corner inflammation suggested a relative risk of 3 to 5 for a new anterior radiographic syndesmophyte at that level.[163-165] The association was even more pronounced in vertebral corners in which the inflammation had resolved following institution of anti-TNF therapy. This might be explained by TNF in an active inflammatory lesion restricting new bone formation, whereas reduction of TNF by application of a TNF-antagonist allows tissue repair to manifest as new bone formation.[164,165] Fat infiltration in the vertebral corners seems to be a key intermediary in the process because its development is linked to resolution of previous inflammation and to future development of syndesmophytes.[166,167]

One study suggests that in early inflammatory back pain, MRI images of severe sacroiliac bone marrow edema, with human leukocyte antigen (HLA)-B27 positivity is a strong

predictor of future AS, whereas mild or no sacroiliitis, irrespective of HLA-B27 status, was a predictor of that AS would not develop in the future.[168] Data on the value of MRI for predicting therapeutic response in SpA are very limited. A high spine MRI inflammation score and short disease duration have been reported as statistically significant predictors of clinical response (BASDAI improvement >50%) to anti-TNF therapy.[169,170] Further and larger studies are needed to clarify the role of MRI in the prediction of disease course and therapeutic response in clinical practice.

## Psoriatic Arthritis

The clinical appearance of PsA is very diverse, involving the spine, SI joints, peripheral joints and/or entheses. Thus MRI findings are variable. PsA shares clinical manifestations with RA and SpA, and this also applies to its features on MRI.[171] Peripheral PsA synovitis and erosions do not have disease-specific features on MRI, and MRI bone edema can involve any bone. A general agreement on which joints to image to assess PsA activity and damage is not established, and possibly needs to be individualized, based on the disease pattern. Whole-body MRI, allowing imaging of both peripheral and axial joints and entheses of the entire body in one examination, may be a future solution to this, but still requires more validation.[96-98]

MRI can visualize both peripheral and axial musculoskeletal anatomy and PsA disease manifestations. Findings include synovitis, tenosynovitis, periarticular inflammation, enthesitis, bone edema, bone erosion, and bone proliferation (Figure 58-23).[172-175] As in other types of SpA, enthesitis, dactylitis and spondylitis can be seen. Dactylitis has been shown on MRI to be caused by tenosynovitis with effusion, sometimes associated with diffuse soft tissue edema and/or synovitis in nearby finger or toe joints (see Figure 58-23).[176,177] There are few MRI studies in axial PsA, but findings are similar to AS findings, although more frequently asymmetric.[178,179]

The entheses has attracted attention as a possible primary location of disease.[180] Nail disease is common in PsA, and DIP joint inflammation seen on MRI has been described to extend to the nail bed.[181]

PsA can be clinically silent. In patients with psoriasis without arthritic signs or symptoms, pathologic findings on MRI (including periarticular edema, tendon sheath effusion, intra-articular effusion, synovial pannus, bone erosion, bone cysts, subchondral changes, and joint subluxation) have been reported in more than two thirds (68% to 92%) versus none to 1/12 or less of healthy controls.[182-184] The clinical importance of these findings is not yet clarified.

### Use in Diagnosis, Monitoring, and Predicting Outcome

**Diagnosis.** As described previously, MRI can detect the different pathologies involved in PsA. However, no studies have documented that MRI in an early undifferentiated arthritis cohort can be used to differentiate PsA from other arthritides.

**Monitoring.** Data on monitoring activity and damage are limited. Most studies only report qualitative MRI assessments of the different pathologies of PsA.[171] Quantitative assessment of contrast enhancement has been reported[185-186] but is insufficiently validated for clinical use. Scoring systems of inflammation and damage have been developed.[172,187,188] The OMERACT Psoriatic Arthritis Magnetic Resonance Image Scoring System (PsAMRIS) is the best

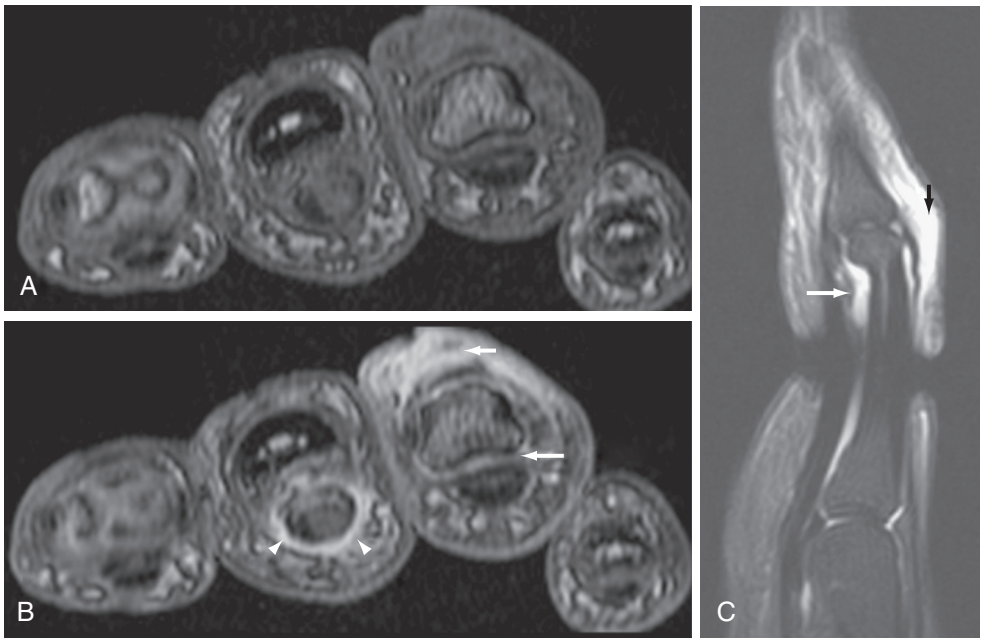

**Figure 58-23 Psoriatic arthritis (MRI).** Axial T1-weighted precontrast **(A)** and postcontrast **(B)** MRI of the second *(left)* through fifth *(right)* fingers at the level of the fourth proximal interphalangeal joint and sagittal short tau inversion recovery MRI **(C)** of the fourth finger show mild synovitis (*long arrows* in **B** and **C**) and considerable periarticular inflammation (*short arrows* in **B** and **C**) around the fourth distal interphalangeal joint and tenosynovitis (*arrowheads* in **B**). *(Courtesy Rene Poggenborg, Glostrup, Denmark.)*

validated and has a documented good intra- and inter-reader reliability and, for inflammatory parameters (synovitis, tenosynovitis, periarticular inflammation), sensitivity to change.[172,189,190] Its usefulness in clinical trials and practice needs further testing.

**Predicting Outcome.** No longitudinal studies of the prognostic value of MRI findings in PsA are available.

## Gout

MRI can directly visualize the inflammatory (synovitis, tenosynovitis, bone edema, and soft tissue inflammation) and destructive (bone erosion) aspects of gout arthropathy.[41,191-193] MRI can also visualize tophi and provide information on the inflammatory nature of these lesions which cannot be appreciated from radiography or CT. On MRI, tophi typically exhibit low signal on T1w images, with varying postcontrast enhancement, and medium-high signal on T2w images, indicating the presence of cellular tissue surrounding or infiltrating the crystalline mass (see Figure 58-6).[191,193] Calcification within the tophus can lead to regions of low signal on T2w images. Tophi are not always clinically detectable if the location is deep to the skin surface.

### Use in Diagnosis, Monitoring, and Predicting Outcome

The diagnostic accuracy of MRI-documented synovitis, bone erosion, and/or tophi against the gout classification criteria[39] has not yet been determined. However, MRI can detect tophi, and the presence of these strongly suggests a diagnosis of gout, but joint aspirate confirmation of monosodium urate crystals is usually required because the differential diagnosis includes infection or other space-occupying lesions.

Monitoring gout by MRI could include assessment of joint inflammation, erosion progression, and extent/size of tophi (see Figure 58-6). Tophus volume assessment by MRI has been reported to have a good intra- and inter-reader reproducibility and may be useful for this purpose in trials.[194] In contrast to RA, AS, and PsA, no MRI scoring system for overall assessment of gouty arthritis has yet been developed.

## Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

MRI detects calcification of hyaline cartilage as an area of low signal intensity, especially on gradient echo images; meniscal chondrocalcinosis exhibits increased signal on T1-weighted and proton density images, and may simulate meniscal degeneration or tear (see Figure 58-7).[195] As in other diseases, MRI is a sensitive method for imaging subchondral cysts and inflammatory changes such as synovitis and effusion.

## Septic Arthritis

The MRI appearance of septic arthritis is nonspecific, and similar findings can be observed in other inflammatory arthritides. Thus, in case of clinical suspicion of septic arthritis, a joint aspiration must be performed without delay to avoid irreversible articular damage. Characteristic findings are synovitis, joint effusion, and soft tissue edema (see Figure 58-8) followed by bone erosion and cartilage destruction. MRI may be helpful in diagnosing complications of septic arthritis, such as abscesses and osteomyelitis. It should be remembered that most of the individual findings on MRI are not specific, and bone marrow edema alone does not necessarily denote osteomyelitis.[196] Contrast-enhanced MRI is particularly useful to identify abscess/necrosis in either soft tissue or bone that may confirm the diagnosis and/or requirement for surgical débridement. Investigation of the painful diabetic foot is a specific clinical presentation for which MRI may now be routinely performed to help distinguish between infection and trauma, and to identify nonviable tissues, although scintigraphic studies also play an important role in these complex patients.[45]

## Osteoarthritis

Based on the tomographic nature and ability to visualize cartilage, bone, and various soft tissues, MRI is very well-suited for assessment of inflammatory changes, structural and compositional changes in the cartilage, and other structural lesions in OA. The majority of studies have been undertaken in knee joints (Figure 58-24) or, less frequently, hip joints, but recently also in small joints in the hand (see Figure 58-10) in generalized OA.

MRI allows direct assessment of the thickness, surface contour, and internal architecture of articular cartilage in OA[197-199] (see Figure 58-24), making the staging and monitoring of OA development possible. Osteophytes at the joint margins or beneath the articular cartilage may be seen. Subchondral changes include bone edema, sclerosis, and bone cysts. MRI bone marrow lesions (sometimes referred to as *bone edema lesions*), which are areas with inhomogeneous, intermediate-low signal on T1w and high signal on water-sensitive techniques (STIR/T2 FS) (Figure 58-25), have, by comparison with histologic samples obtained by surgery in advanced OA, shown trabecular microfracture and bone marrow fibrosis and/or necrosis, but limited interstitial edema.[200-203] Synovitis is seen frequently by MRI in OA, albeit to a lesser degree than in RA.[204] Synovitis scores obtained by contrast-enhanced MRI have demonstrated a good correlation with arthroscopic and microscopic synovitis scores.[205]

### Use in Diagnosis, Monitoring, and Predicting Outcome

**Diagnosis.** The classification criteria for OA are based on clinical and conventional radiographic findings.[48] However, the use of MRI in the diagnosis of OA offers the advantages described in preceding text (i.e., that MRI can sensitively depict all the involved pathologic changes).

**Monitoring.** Various quantitative and semiquantitative techniques have been used to measure structural abnormalities and changes on MRI in OA.[197] Quantitative measurements apply computer-aided image processing to quantitate various aspects (e.g., volumes of cartilage, bone, bone marrow lesions, menisci, or synovium. These have been reported to have excellent reproducibility).[206] Measures of cartilage composition are also available (e.g., quantification of glycosaminoglycan content).[198,199] See the previous paragraph on the technical aspects of MRI, for other potential

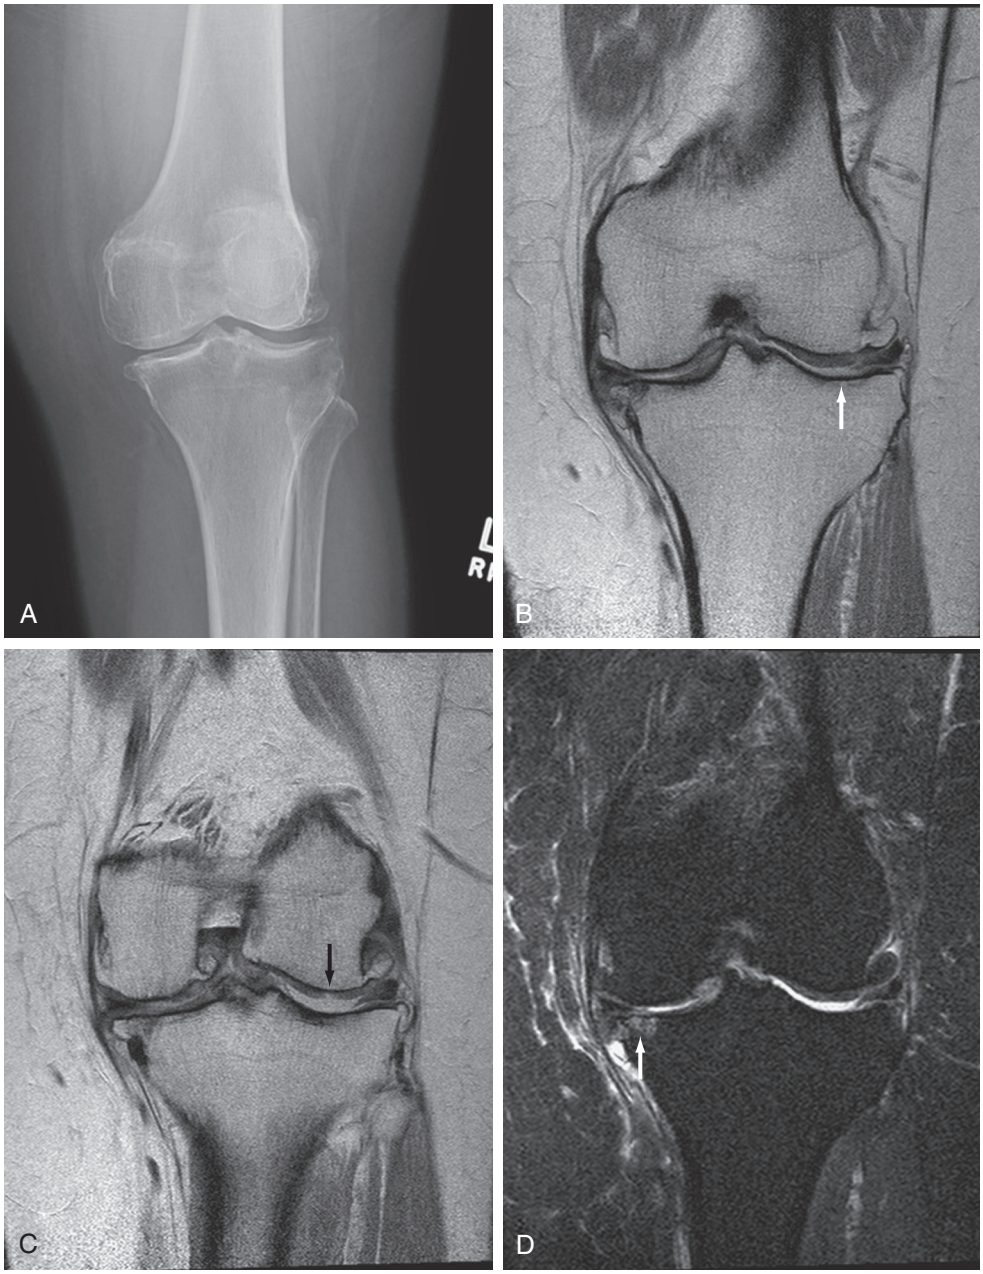

**Figure 58-24 Osteoarthritis of the knee (radiography and MRI). A**, Anteroposterior radiographic view of the left knee shows large osteophyte of the medial and lateral tibiofemoral joint and mild medial joint space narrowing. **B** and **C,** Coronal proton density-weighted MRI confirms the presence of large osteophytes in the tibiofemoral joint, shows diffuse cartilage loss of the medial tibia and femur, and discloses a denuded bone with complete loss of cartilage in the lateral tibial plateau (*arrow* in **B**). A small focal cartilage defect of the lateral femoral condyle (*arrow* in **C**) is also evident. Both lateral and medial menisci are partially macerated, and a subluxation of the medial meniscus is seen, along with severe cartilage loss on the medial and lateral tibial plateau and the medial femoral condyle. **D**, Coronal T2-weighted fat-suppressed MRI shows medial tibial plateau subchondral bone marrow edema (*arrow* in **D**). *(Courtesy Professor Ali Guermazi, Boston, Mass.)*

methods. Semiquantitative methods have been used to provide semiquantitative "multiple feature" ("whole-organ") assessments in the knee, based on conventional MRI acquisitions.[207-210] These measures have high reliability and better sensitivity to change than radiographic methods.[206] A system for systematic assessment of hand OA has also been developed and validated.[211]

**Predicting Outcome.** In a systematic literature review[212] quantitative cartilage volume change and presence of cartilage defects or bone marrow lesions (bone edema) in three of three studies was significantly related to subsequent total knee replacement (i.e., a predictive value was demonstrated).[213-215]

Furthermore, enlargements in bone marrow lesions have been demonstrated to be related to increased pain (and improvements in bone marrow lesions to decreased pain) in follow-up studies.[216,217] In contrast, an inconsistent and generally weak association between cartilage loss and symptom change, and a weak association between change in synovitis and change in pain have been reported. Finally, the presence of meniscal damage, cartilage defects, and/or BMLs predicts subsequent MRI-visible progression of disease.[212]

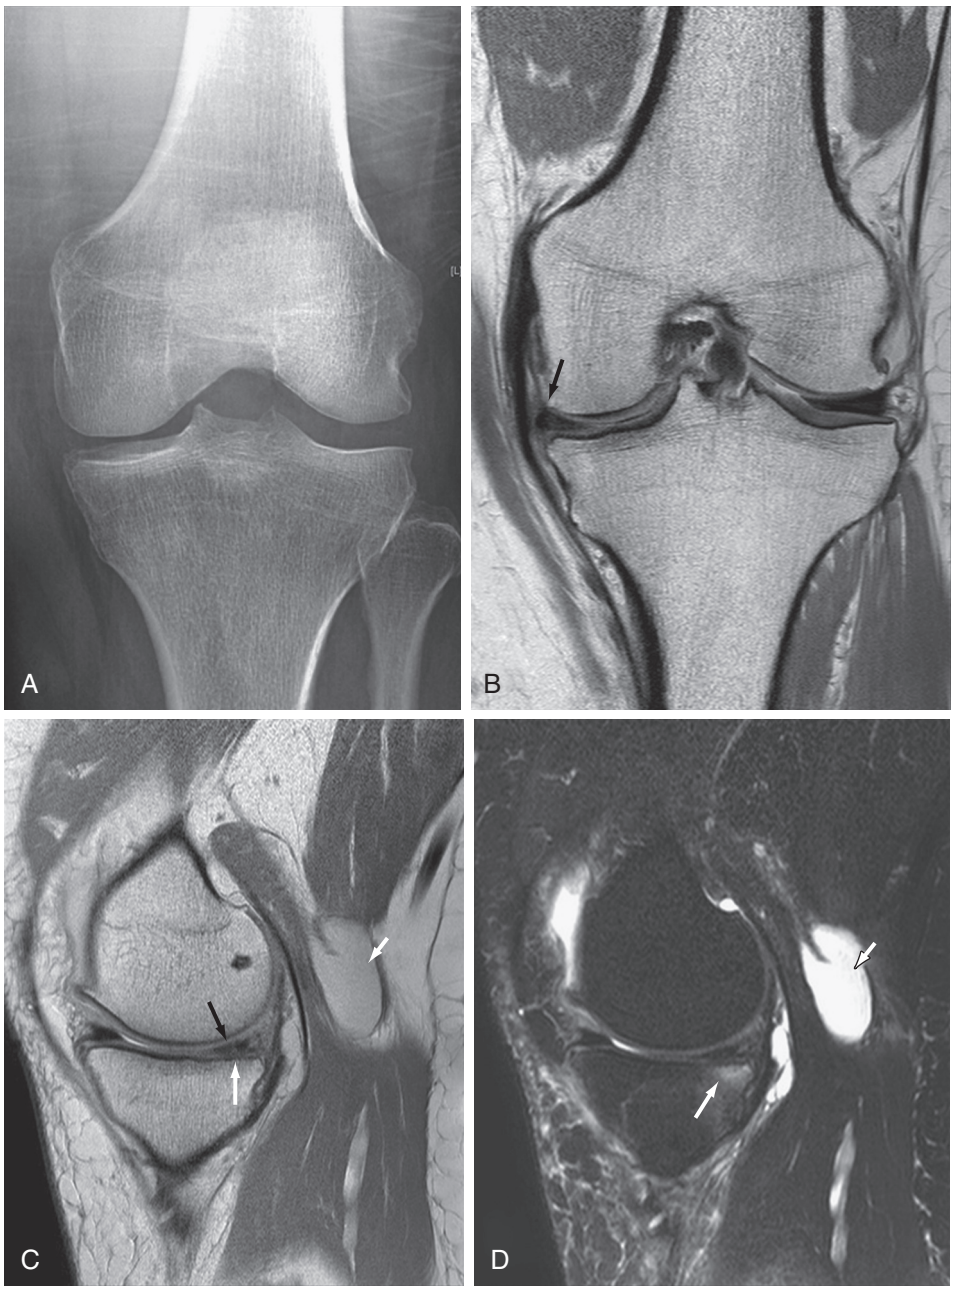

**Figure 58-25 Early osteoarthritis (OA) of the knee (radiography and MRI).** Radiography **(A)** and MRI (**B** through **D**) of the knee with early OA. **A,** Anteroposterior radiographic view shows an almost normal knee. The only possible abnormality is a tiny osteophyte at the medial tibial plateau. **B,** Coronal proton density-weighted MRI shows a minimal medial meniscus subluxation *(arrow)*. **C**, Sagittal proton density-weighted MRI shows partial maceration of the posterior horn of the medial meniscus *(black arrow)*, thinning of the cartilage at the posterior medial tibial plateau *(long white arrow)*, and a moderate-sized Baker's cyst *(short white arrow)*. **D,** Sagittal fat-suppressed T2-weighted MRI confirms the Baker's cyst *(short arrow)* and also shows subchondral bone marrow edema *(long arrow)* subjacent to the loss of cartilage at the posterior subregion of the medial tibial plateau. *(Courtesy Professor Ali Guermazi, Boston, Mass.)*

## ULTRASONOGRAPHY

### KEY POINTS

- Ultrasonography allows sensitive visualization and assessment of peripheral inflammatory and destructive joint and soft tissue involvement in a variety of degenerative and inflammatory rheumatic diseases.
- Ultrasonography can readily be performed by trained rheumatologists in relation to the clinical examination.
- Ultrasonography can, through detection of early inflammatory changes, contribute to earlier diagnosis of RA.
- Grey scale and power Doppler ultrasonography allow physicians to monitor inflammatory soft tissue changes (e.g., synovitis, tenosynovitis, and enthesitis) during treatment of patients with peripheral inflammatory joint diseases.
- Ultrasonography allows guidance of invasive procedures, making possible precise needle positioning for aspirations and injections (e.g., in joints, bursae, or tendon sheaths, or at entheses).
- The main disadvantages of ultrasonography are the need for a skilled operator interreader and interscanner variability, and the need for an "acoustic window."

Ultrasonography is an evolving imaging technique increasingly used by rheumatologists in daily clinical practice. This fact is confirmed by extensive publications and a wide body of literature during the last few years.[218,219] In some countries, including Belgium, Italy, Germany, Spain, and the United States, ultrasonography has become an integral part of rheumatology training. Absence of radiation, good visualization of the joint cavity, low running costs, multiplanar imaging capability, quantification of soft tissue abnormalities and real-time assessment are the main advantages of ultrasonography, compared with other imaging techniques. Moreover, ultrasonography is rapidly performed, readily accepted by patients, and increasingly used for guidance of invasive procedures (biopsy, joint aspiration, and injection).[220] It has been reported that ultrasonography increased the confidence in physicians' recommendations in 88.4% of RA patients.[221]

Ultrasonography provides a clear view of the anatomic damage induced by inflammatory or degenerative conditions and allows an accurate assessment of joint and soft tissue involvement in a variety of rheumatic diseases including RA, juvenile idiopathic arthritis, AS, and other spondyloarthritides, crystal deposition diseases, septic arthritis, SLE, entrapment neuropathies, systemic sclerosis, polymyositis, Sjögren's syndrome, vasculitis, OA, and regional pain syndromes (Figure 58-26).

Ultrasonography is rapid, safe, and very useful as guidance for invasive procedures.[220,222,223] Ultrasound-guided needle placement within the selected target area is an accurate and safe approach for patients requiring aspiration of synovial fluid, injection therapy, or biopsies. Under ultrasound guidance, the progression of the needle in the soft tissues toward the selected target area can be carefully controlled, therefore avoiding injury induced by the tip of the needle and/or complications such as subcutaneous or intratendinous injection of corticosteroid which has a high risk of tissue damage. Moreover, ultrasound-guided injections

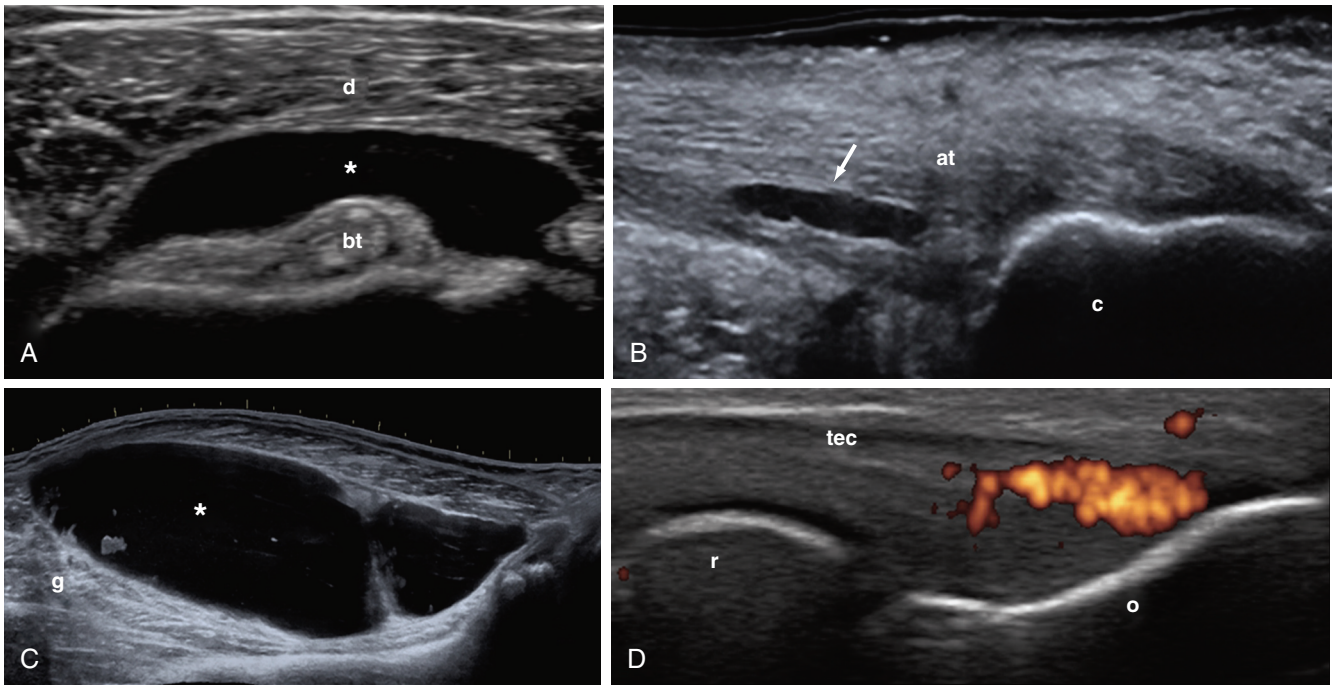

**Figure 58-26 Various regional pain syndromes (ultrasonography). A,** Shoulder (anterior transverse scan): fluid collection in the subdeltoid bursa *(asterisk)*. **B,** Achilles tendon *(at)* (longitudinal scan): large tendon tear *(arrow)*. **C,** Knee (posterior longitudinal scan): massive fluid collection inside the semimembranosus gastrocnemius bursa (popliteal cyst) *(asterisk)*. **D,** Elbow: epicondylitis characterized by intense power Doppler signal within the common extensor tendon of the fingers (tec). *bt*, Long head of the biceps tendon; *c*, calcaneous; *d*, deltoid muscle; *g*, gastrocnemius muscle; *o*, lateral epicondyle; *r*, radial capitellum.

for inflammatory arthritis are significantly less painful than palpation-guided models, and even though recent studies have not been able to demonstrate significantly improved clinical outcomes,[224,225] it is likely that ultrasound guidance will ultimately be shown to improve clinical outcomes and enhance cost effectiveness.

Ultrasonography can be used in daily rheumatology practice for a wide spectrum of indications (see Key Points for ultrasonography). In a recent study, the additional information obtained by ultrasonography led to changes in diagnosis in 60% of areas examined (compared with diagnoses made without ultrasonography, based solely on clinical examination) and changes in treatment in 28% of patients.[226]

## Technical Aspects

Musculoskeletal ultrasonography requires high-quality equipment. Low-frequency transducers (3.5 to 5 MHz) are useful to explore deep targets (e.g., the hip and sacroiliac joints). Medium-frequency transducers (6 to 13 MHz) are the best choice to explore large joints (the shoulder, knee, and elbow). High-frequency transducers (14 to 20 MHz) have a low penetration power of the ultrasonic beam but allow for an accurate assessment of superficial structures (tendons and finger joints), reaching a resolution power of less than 0.1 mm.

Ultrasonography is an operator-dependent technique. Thus, the quality of the pictures and the interpretation of sonographic images depend on the quality of the ultrasonography equipment, the technical conditions of the examination, and the skills and experience of the examiner.

Color Doppler and power Doppler ultrasonography explore blood perfusion and may play a key role in the monitoring of inflammatory disease activity and the assessment of response to therapy.[227] Color Doppler provides information on the direction of blood flow. Power Doppler has greater sensitivity in detecting blood flow, but is not able to determine either flow direction or velocity. The use of ultrasonography contrast agent enhances the detection of tissue vascularity with Doppler ultrasonography, which may have an effect on the detection of subclinical synovitis.[228] However, the use of ultrasonography contrast agents for the assessment of rheumatic diseases remains restricted to the research field, both for ethical and cost/efficacy reasons.

Ultrasonography is a continuously evolving technique, and recent advances in technology promise further improvements, especially in the field of 3D, four-dimensional (4D) ultrasonography, elastosonography, and fusion imaging.[229] 3D ultrasonography has the potential to dramatically reduce the duration of ultrasonography examination and to improve the standardization of the technique. Longitudinal, transverse, coronal planes, and 3D reconstruction of the target area can be acquired in a few seconds.[229] Elastosonography is a new technique to assess tissue elasticity. Its main potential applications in rheumatology include skin assessment in systemic sclerosis, evaluation of tendon stiffness, and differential diagnosis of subcutaneous nodules. Fusion imaging allows simultaneous comparison and mapping of ultrasound images onto another preacquired imaging modality, such as CT or MRI.

## Examination Technique

Ultrasonography examination of the musculoskeletal system should be performed with multiplanar scans. The EULAR guidelines were designed to standardize the approach to musculoskeletal ultrasonography in rheumatology.[230]

The patient position is critical for a correct ultrasound examination. For example, examinations to detect synovial fluid in a patient's knee joint should be performed with a suprapatellar scan of the knee in 30 degree flexion.[231] Particular attention must be paid to the angle of the ultrasound beam, which must be perpendicular to the examined structure to avoid anisotropy-dependent artifacts (spatial asymmetry). These artifacts may generate diagnostic errors, especially when the physician is studying fibrillar or fascicular structures such as tendons and nerves. Both longitudinal and transverse scans should be performed by slightly moving the transducer from the radial to ulnar and from the proximal to distal sides to enable maximum coverage of the anatomic surface area.

Operator dependency is the main shortcoming of ultrasonography. Adequate supervised training is essential to ensure the correct use of ultrasonography and appropriate interpretation of results. Another limitation of ultrasonography is in the comprehensive assessment of some anatomic areas (i.e., the spine, sacroiliac joint, and hip) resulting from the lack of adequate "acoustic windows." Pitfalls and errors are mostly related to misinterpretation of normal anatomy, inadequate regulation of the ultrasonography beam, and inappropriate examination techniques, mainly depending on pressure, position, and inclination of the probe. Grey scale and Doppler findings require a careful analysis that should also take account of the pharmacologic treatment. Glucocorticosteroids and biologic agents have the strongest potential to modify ultrasonography findings, but even nonsteroidal anti-inflammatory drugs may decrease grey scale and power Doppler synovitis scores.[232] Ultrasonography findings provide a wide range of useful information concerning the main tissue changes occurring in patients with rheumatic diseases. However, limited standardization still exists about scanning methodology and definitions of basic sonographic abnormalities. Questions such as which joints should be scanned or which scoring system should be used are still a matter of discussion.[233] The most widely accepted definitions for sonographic pathology in patients with RA, were published in 2005 by the OMERACT special interest group (Table 58-4).[234] An expert consensus paper on ultrasonography definition and scoring of tenosynovitis, that used a four-grade semiquantitative scoring system, was recently published, describing a four-grade semiquantitative scoring system which has shown high interobserver agreement (grey scale agreement, 87.5%; Doppler agreement, 96.3%).[235] Criteria of ultrasound remission are still not well defined. Power Doppler seems to be the most promising candidate method, even though the minimal acceptable level of power Doppler activity is unknown.[233]

## Rheumatoid Arthritis

RA is the inflammatory condition most frequently studied by ultrasonography. Ultrasound abnormalities detected in patients with RA include joint space widening, fluid

collection, synovial hypertrophy, cartilage defects, bone erosions, tendon sheath widening, and tendon tears.[236] Joint cavity widening is the earliest characteristic ultrasound finding of synovitis. Even minimal intra-articular fluid collection and synovial proliferation may be easily revealed by ultrasonography. Fluid collection shows a typical anechoic pattern that can easily be distinguished from the soft echogenicity of synovial hypertrophy. This appears as a homogeneous thickening of the synovial layer or as irregularly shaped clusters of echoes (bushy and villous appearance). Doppler signal may be particularly intense inside the areas of synovial hypertrophy in patients with active synovitis. Doppler signal is associated with the extent of inflammation detectable in the synovial biopsies in patients with RA.[237]

**TABLE 58-4** Definitions of Ultrasonographic Pathology in Inflammatory Joint Disease*

| |
|---|
| **Bone erosion.** An intra-articular discontinuity of the bone surface that is visible in two perpendicular planes. |
| **Synovial fluid.** Abnormal hypoechoic or anechoic (relative to subdermal fat, but sometimes isoechoic or hyperechoic) intra-articular material that is displaceable and compressible, but does not exhibit Doppler signal. |
| **Synovial hypertrophy.** Abnormal hypoechoic (relative to subdermal fat, but sometimes isoechoic or hyperechoic) intra-articular tissue that is nondisplaceable and poorly compressible and which may exhibit Doppler signal. |
| **Tenosynovitis.** Hypoechoic or anechoic thickened tissue with or without fluid within the tendon sheath, which is seen in two perpendicular planes and which may exhibit Doppler signal. |
| **Enthesopathy.** Abnormally hypoechoic (loss of normal fibrillar architecture) and/or thickened tendon or ligament at its bony attachment (may occasionally contain hyperechoic foci consistent with calcification), seen in two perpendicular planes that may exhibit Doppler signal and/or bony changes, including enthesophytes, erosions, or irregularity. |

*From OMERACT (Outcome Measures in Rheumatology) ultrasonography task force.[234]

The assessment of perfusion of synovial tissue may prove to be the most important part of evaluation of joints in patients with RA. Differentiation between inactive and persistent inflammation in the rheumatoid joint is one of the most important problems for the clinician because it may have a great impact on clinical decision making.

The detection of a highly perfused synovial pannus in a patient with early-stage arthritis should be regarded as a potential predictor of future anatomic damage (Figure 58-27). Ultrasonography can also be used to assess cartilage damage at the metacarpophalangeal joint level in patients with RA (Figure 58-28). The level of grey scale synovitis correlates with disease duration, whereas the presence of power Doppler is independent of disease duration, and thus may be a better marker of inflammation at any given time.[233]

The high spatial resolution of ultrasonography allows for the recognition of even minimal bone erosions. The sensitivity is highest in easily ultrasound-accessible areas, including the frequently involved second metacarpophalangeal

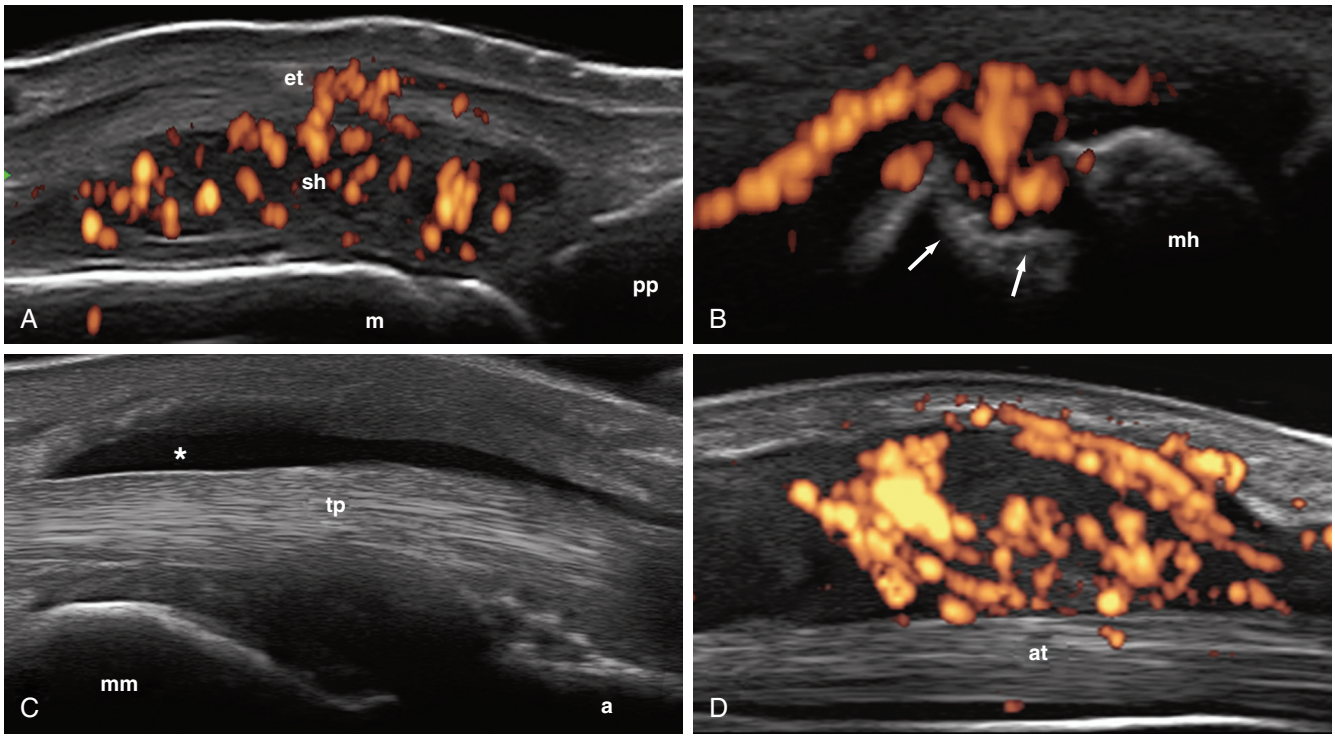

**Figure 58-27 Rheumatoid arthritis (ultrasonography). A,** Metacarpophalangeal joint (dorsal longitudinal scan): joint cavity widening, synovial hypertrophy *(sh)*, and intense power Doppler signal. **B,** Fifth metatarsophalangeal joint (lateral longitudinal scan): large bone erosion *(arrows)* associated with power Doppler signal inside the erosion. **C,** Tibialis posterior tendon *(tp)*: tendon sheath widening with homogeneous anechoic aspect of the content (fluid collection) *(asterisk)*. **D,** First compartment of the finger extensor tendons (longitudinal scan): chronic tenosynovitis characterized by synovial hypertrophy and intense power Doppler signal. *a*, Astragalus; *at*, abductor pollicis longus tendon; *et*, common extensor tendon of the finger; *m*, metacarpal bone; *mh*, metatarsal head; *mm*, medial malleolus; *pp*, proximal phalanx.

and fifth metatarsophalangeal joint.[52,238,239] Ultrasound bone erosions are most frequently found at the fifth metatarsal head in patients with early-stage RA.[240] Bone erosions are viewed on ultrasound as an interruption of the sharp hyperechoic bone profile. Ultrasonography depicts the wall and the floor of the erosions, which in most cases are filled by a hyperperfused synovial pannus. It has been demonstrated that ultrasonography is able to detect more erosions than radiography, especially in early-stage RA, and that erosions detected with ultrasonography are true erosions compared with those detected with CT as the gold standard.[52,53,241] However, some of the smallest bone erosions detected by ultrasonography do not correspond to cortical bone breaks seen on micro-CT. These false-positive findings correspond to bone channels and forceps-like osteophytes.[242]

Tendon involvement is frequent and characteristic in patients with RA. The spectrum of pathologic changes detectable in tendons by ultrasonography is wide and heterogeneous. Tendon sheath widening, loss of the normal fibrillar echotexture and loss of definition of tendon margins, and partial or total tears are the abnormalities that characterize tenosynovitis.[236] Circumscribed or extensive collections of anechoic fluid within the synovial sheath is the most characteristic feature of exudative tenosynovitis. The presence of echoes within the tendon sheath can be associated with synovial proliferation and/or aggregates of cells and proteins.

Very subtle changes in tendon structure can be detected in patients with early-stage RA. The predictive value of these changes in detecting the more aggressive or rapidly progressive forms of disease has still not been clearly defined, and follow-up investigations are needed. Tenosynovitis at the extensor carpi ulnaris tendon seems to predict the development of erosions.[243] Early circumscribed tendon tears appear as minimal fragmentation of small groups of contiguous fibrils, which determines a characteristic loss of the normal fibrillar echotexture of the tendon. In the more advanced stages of structural damage, tendons can exhibit large partial tears or complete rupture. A three-grade semiquantitative score (normal, partial, and complete rupture) seems to be the best approach to the ultrasound assessment of tendon damage in patients with RA.[244] If the ultrasound beam and the major axis of the tendon are not perfectly perpendicular, certain areas of the tendon appear anechoic (anisotropy artifacts) and thus may be mistaken for possible tendon ruptures.

Ultrasonography is more sensitive than clinical examination for the detection of arthritis. A significantly higher number of inflamed joints are found by ultrasonography than by clinical assessment. However, ultrasound examination of 78 joints requires 70 minutes, and the time needed for even a seven-joint set can be challenging in daily clinical practice.[245,246]

### Use in Diagnosis, Monitoring, and Predicting Outcome

**Diagnosis.** The ability of ultrasonography to visualize intra- as well extra-articular changes suggests that it could be used to assist clinicians in reaching a specific diagnosis (e.g., in patients with early undifferentiated arthritis). The data describing the differential diagnostic value in patients with undifferentiated arthritis are, however, very limited. In the seronegative (RF and anti-citrullinated protein antibody [ACPA] negative) subgroup of 50 early undifferentiated inflammatory arthritis patients, certain clinical and radiographic features (elevated CRP, swollen joints, and radiographic erosion) raised the probability of persistent

inflammatory arthritis from 6% to 30%, whereas further addition of 1 to 3 specific ultrasound features (grade 3 grey-scale synovial hypertrophy, at least grade 2 synovial power Doppler signal, and at least one erosion) increased the probability to 50% to 94%, suggesting that combining ultrasonographic evaluation with routine assessment in seronegative early arthritis may markedly increase the certainty of diagnosis.[247] In seropositive disease (RF and/or ACPA positive), ultrasonography had no predictive value. In another study, ultrasonography was recently demonstrated to improve, compared with clinical joint examination, the accuracy of the 2010 ACR/EULAR criteria for identifying patients with a disease that requires methotrexate treatment.[248] The exact position of ultrasonography in the diagnosis of RA needs further clarification.

**Monitoring Disease Activity and Damage.** Although no international consensus yet exists on the best possible scoring system and which joints to score in the assessment of synovitis and other joint pathologies in RA,[246,249] the OMERACT ultrasonography task force has developed definitions for various joint pathologies, which can be used for further development and validation. Ultrasound measures of synovitis (Doppler signal and B-mode synovial membrane thickness), decrease in parallel with other markers of disease activity when glucocorticoids[227,228,250-252] or TNF-antagonists[253-258] are administered, indicating their potential for monitoring joint inflammation in RA.[259] Ultrasonography visualizes cartilage changes and bone erosion in accessible areas,[260-263] but data are still lacking on reproducibility and sensitivity to change.

Thus, ultrasonography is probably a valid method for monitoring synovitis and, in accessible areas, damage progression. However, the relative advantage of ultrasonography versus radiography for showing damage progression remains unclear, and more data on reproducibility (e.g., probe positioning, selection of site for the picture, machine selection, machine/pressure adjustments) and sensitivity to change when the entire ultrasound examination is repeated, are needed.

**Predicting Outcome.** Data on the predictive value of ultrasound findings are ambiguous. One study has found ultrasound synovitis to be predictive of future radiographic progression in patients treated with conventional DMARDs but not with anti-TNFs,[256] whereas another found no significant correlation between the baseline clinical, laboratory, functional, and ultrasound parameters, and the 1-year follow-up disease activity score (DAS)28, Health Assessment Questionnaire (HAQ) score, and radiographic scores in DMARD treated patients.[264]

The Leeds group has reported that ultrasound and MRI signs of joint inflammation are frequent in patients in clinical remission.[144,265-268] Baseline ultrasound synovial hypertrophy, ultrasound power Doppler, and MRI synovitis scores in individual joints were significantly associated with progressive radiographic damage. Furthermore, there was a significant association between the power Doppler score at baseline and structural progression during 12 months in asymptomatic MCP joints and 12 times higher odds of structural progression in joints with increased power Doppler signal.[142,268] Subsequent studies have supported the value of ultrasonography as an independent predictor of radiographic progression in patients with RA in remission.[269,270] Regarding whether ultrasonography findings in RA patients in clinical remission can predict clinical outcome, one study reported that ultrasonography power Doppler signal was a predictor of flare during continued DMARD therapy,[271] whereas two studies of RA patients in clinical remission on biologic therapy presented conflicting reports on whether ultrasonography could predict who could stop biologic therapy without clinical flare.[272,267] It remains to be determined whether ultrasonography can predict long-term clinically significant disease progression and preservation of clinically important function better than traditional clinical or serological scores, and whether ultrasonography and/or MRI should be incorporated in future treat-to-target strategies.[273]

## Ankylosing Spondylitis/Axial Spondyloarthritis

Despite the fact that contrast-enhanced Doppler ultrasonography has been reported to have a high negative predictive value for the detection of sacroiliitis,[274] the role of ultrasonography in assessment of sacroiliac and spine involvement in AS and other types of axial SpA is minimal.

AS and other types of axial SpA frequently involve peripheral joints and entheses. Ultrasonography of peripheral involvement in SpA is described in the section on PsA that follows.

## Psoriatic Arthritis

Ultrasonography assessment of patients with PsA should be focused on joints, tendons with and without a synovial sheath, entheses, skin, and nails (Figure 58-29).[275] Basic sonographic changes of joint and synovial tendons can be similar to those of RA. However, a highly hypervascularized pannus seems to be more prominent in PsA patients, both in small and large joints. This feature appears to be related to histopathologic findings.[276] Tendons without synovial sheaths are characteristically involved in PsA. Inflammatory changes detectable by ultrasonography include loss of fibrillar echotexture, focal, or diffuse hypoechoic tendon thickening caused by intratendinous edema, with or without power Doppler signal. Moreover, a peritendinous inflammation may appear as a hypoechoic swelling of the soft tissue surrounding the tendon which may show power Doppler signal.[277]

Ultrasonography can detect a wide range of abnormalities of the enthesis. These consist of entheseal thickening, focal hypoechogenicity, loss of the homogeneous fibrillar echotexture, irregularity of the bone profile (enthesophytes and/or bone erosions), and power Doppler signal. There is evidence to support the use of ultrasonography as a very sensitive tool to detect subclinical enthesopathy in patients with psoriasis and no clinical signs of arthritis and/or enthesitis. An international consensus-based ultrasonography definition of enthesitis has recently been published.[278] The hyperechoic thickening of the epidermis with or without acoustic shadowing and the hypoechoic swelling of the dermis with evident power Doppler signal are the main ultrasound features of psoriatic plaque. Both the nail plate and bed can be accurately depicted by ultrasonography, and a wide range of abnormalities can be detectable, including thickening and loss of the typical trilaminar aspect of the

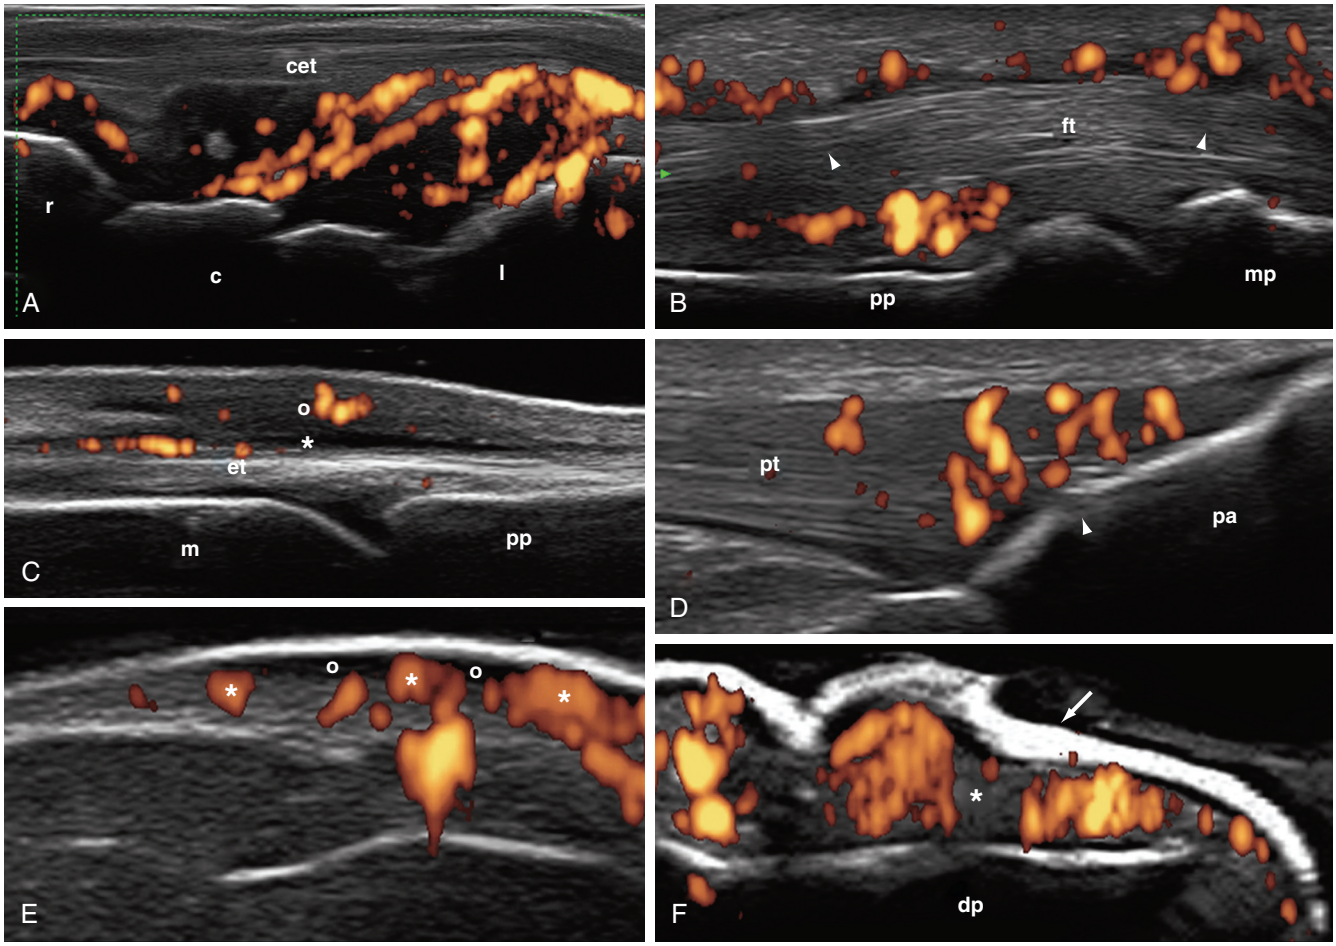

**Figure 58-29** **Psoriatic arthritis (ultrasonography). A**, Wrist (dorsal longitudinal scan): marked joint cavity widening of both radiocarpal and intercarpal joints with intense power Doppler signal. **B**, Proximal interphalangeal joint (longitudinal volar scan): chronic tenosynovitis with areas of low tendon echogenicity *(arrowheads)* and power Doppler signal. **C,** Metacarpophalangeal joint (dorsal longitudinal scan): peritendinous inflammation characterized by hypoechoic swelling surrounding the extensor digitorum tendon *(asterisk)* associated with power Doppler signal and subcutaneous edema *(circle)*. **D**, Distal patellar enthesis (longitudinal anterior scan): thickening of the enthesis associated with intense power Doppler signal and bone erosion *(arrowhead)*. **E**, Psoriatic plaque: hypoechoic subepidermal thickening *(circle)* with intense power Doppler signal *(asterisk)* indicating vasodilatation and angiogenesis. **F**, Psoriatic onychopathy: loss of the normal trilaminar aspect of the nail plate *(arrow)*, thickening of the nail bed *(asterisk)*, and intense power Doppler signal. *c*, Capitate; cet, common extensor digitorum tendons; *dp*, distal phalanx; *et*, common extensor tendon of the finger; *ft*, flexor finger tendons; *l*, lunate; *m*, metacarpal bone; *mp*, middle phalanx; *pa*, patella; *pp*, proximal phalanx; *pt*, patellar tendon; *r*, radius.

nail plate with or without increased Doppler signal at the nail bed.[275]

Power Doppler synovitis is correlated with PsA-specific composite scores such as the Disease Activity Index for Psoriatic Arthritis (DAPSA) and the Composite Psoriatic Disease Activity Index (CPDAI). Conversely, ultrasound signs of enthesitis, dactylitis, tenosynovitis, and perisynovitis are not associated with clinical composite scores.[279]

### Use in Diagnosis, Monitoring, and Predicting Outcome

**Diagnosis.** Ultrasonography is more sensitive than clinical examination for detection of synovitis, tenosynovitis, and enthesitis in patients with PsA[280-282] but no studies have yet documented that ultrasonography in an early undifferentiated arthritis cohort can be used to differentiate PsA from other arthritides. Because enthesitis is prominent in SpA patients and may precede joint symptoms, it has been of interest to evaluate the entheses by use of ultrasonography as a means of diagnosing SpA and therefore also PsA.[283]

A recent study indicates that early ultrasonography enthesitis will predict development of SpA.[284] Further work is needed to clarify the role of ultrasonography in the diagnosis of PsA.

**Monitoring.** Most studies which aim to monitor treatment response have applied semiquantitative scoring systems for grey-scale and/or Doppler changes.[285,286] TNF blocker treatments have provided significant reduction in both grey-scale and Doppler semi-quantitative synovitis scores,[285] in entheseal morphologic abnormalities, power Doppler signal, and in bursitis.[287] Several systems to assess enthesitis have been proposed.[288-290] No system has been sufficiently validated to be used for monitoring PsA or other spondyloarthritides. More research is needed before standardized, reliable, and responsive ultrasonography outcome measures in PsA are available.

**Predicting Outcome.** No studies currently exist that evaluate the role of ultrasonography for prognosticating PsA. Entheseal involvement in patients with psoriasis, but without clinical PsA, indicate that enthesitis may be a

predictor of development of PsA.[291] However, longitudinal studies are required to clarify this.

## Gout

Ultrasonography can detect monosodium urate crystal deposition on the cartilage surface, inside the joint cavity, and around and inside tendons. The spectrum of ultrasound appearance of urate crystal aggregates can vary from homogeneously punctate to sharply defined hyperechoic densities of variable size and, eventually, to dense tophaceous material with posterior acoustic shadows.[292] Joint cavity widening is the most frequent ultrasound finding in patients with acute gout. The sensitivity of ultrasonography is comparable to that of DECT for the diagnosis of gouty arthritis, but ultrasonography is more cost effective and does not expose the patient to radiation.[293]

Monosodium urate crystal deposition on the surface of the articular cartilage results in hyperechoic enhancement of the chondrosynovial margin, which can range from homogeneous thickening of the chondrosynovial interface to areas of focal deposition.[294] Bone erosions are frequently detectable in patients with chronic gout.

Asymptomatic and symptomatic involvement of tendons is common in patients with gout. Urate crystals aggregates of variable size and shape are frequently detectable, especially at the patellar and the Achilles tendons. The normal fibrillar echotexture of tendons can be completely altered by the presence of intratendinous monosodium urate deposits, which appear as areas of inhomogeneous echogenicity sometimes generating an acoustic shadow (Figure 58-30).[294]

### Use in Diagnosis, Monitoring, and Prognostication

The detection of tophi could be helpful in diagnosing gout, especially when these lesions are not detectable clinically. Detection of a nodule with characteristic appearance on

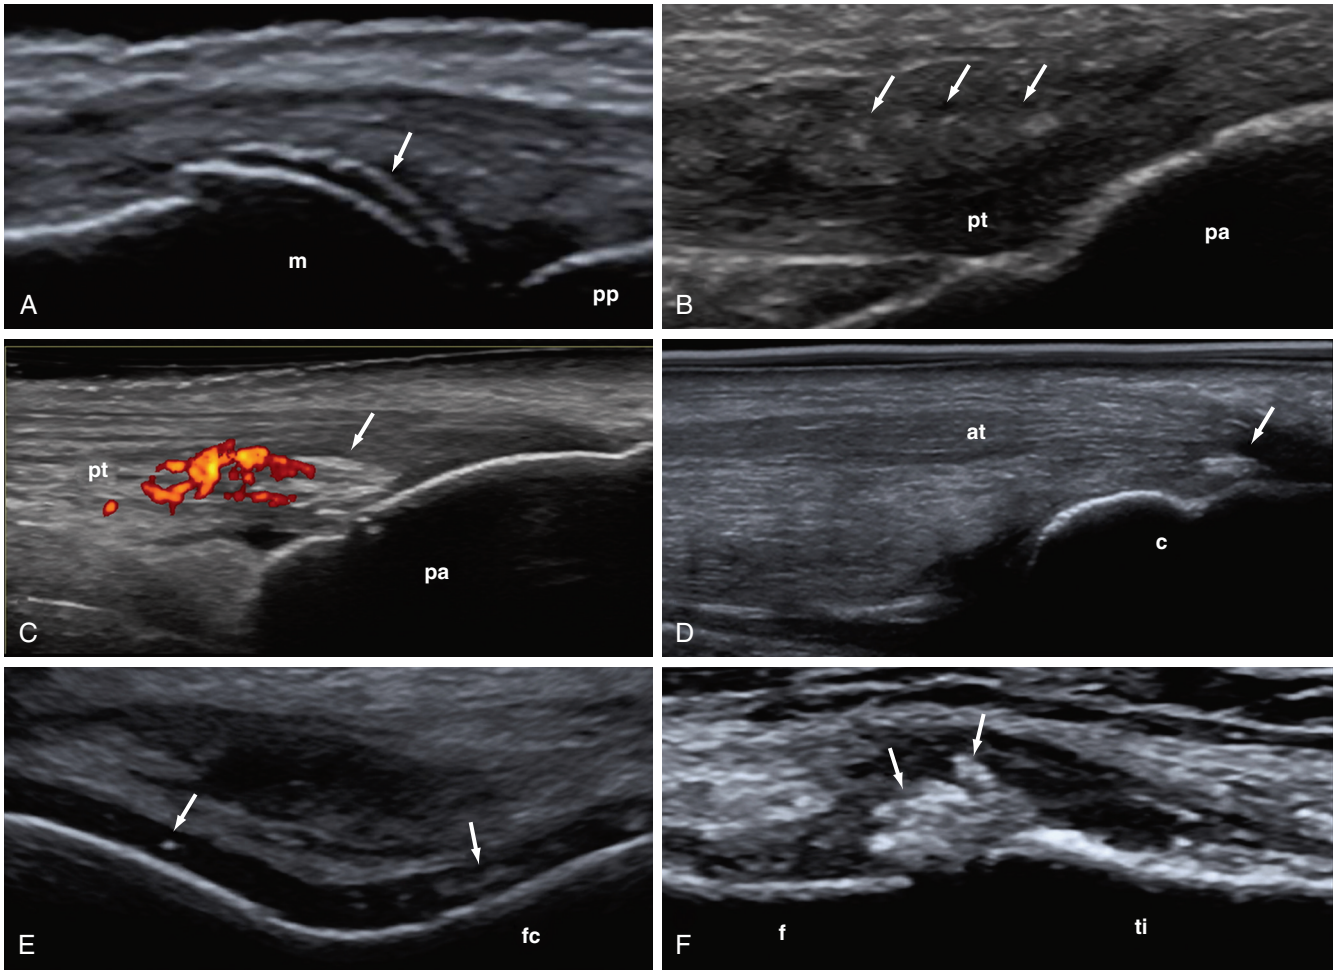

**Figure 58-30 Gout and calcium pyrophosphate dihydrate (CPPD) crystal deposition disease (ultrasonography). A** through **C,** Gout. **A,** Chronic gout. Metacarpophalangeal joint (longitudinal scan with fingers in full flexion): hyperechoic enhancement of the chondrosynovial interface *(arrow)* caused by monosodium urate crystal deposition. **B,** Distal patellar enthesis (longitudinal anterior scan): intratendinous monosodium urate deposits *(arrows)*. **C,** Distal patellar enthesis (longitudinal anterior scan): tophaceous deposits *(arrow)* surrounded by power Doppler signal. **D** through **F**, CPPD crystal deposition disease. **D,** Achilles tendon *(at)* (longitudinal scan): intratendinous linear hyperechoic deposits without acoustic shadow *(arrow)*. **E**, Femoral hyaline cartilage (transverse scan): calcium pyrophosphate deposits within the hyaline cartilage *(arrows)*. **F,** Knee (longitudinal lateral scan): diffuse meniscal calcification *(arrows)*. *c*, Calcaneus; *f*, femur; *fc*, femoral condyle; *m*, metacarpal head; *pa*, patella; *pp*, proximal phalanx; *pt*, patellar tendon; *ti*, tibia.

ultrasound, MRI, or CT is highly suggestive of gout, and the double contour sign, expected to represent urate crystals on the cartilage surface, has been shown to have diagnostic value.[295,296] Nevertheless, joint aspirate confirmation of monosodium urate crystals is usually required to rule out infection or other space-occupying lesions. Tophus size can be reliably assessed by ultrasonography and may be useful for monitoring treatment efficacy in clinical trials.[194,292] An ultrasonography scoring system for overall assessment of gout has not yet been formalized but is under development.[296] The prognostic value of ultrasonography findings is not known.

## Calcium Pyrophosphate Dihydrate Crystal Deposition Disease

Ultrasonography has been found to be highly sensitive in detecting aggregates of CPPD crystals.[294,297] CPPD aggregates range from tiny circumscribed hyperechoic spots to extended deposits with or without acoustic shadow. Based on case control studies,[297,298] a EULAR task force for the development of recommendations for calcium pyrophosphate deposition disease has concluded that "US [ultrasonography] can demonstrate CPPD in peripheral joints, appearing typically as thin hyperechoic bands within hyaline cartilage and hyperechoic sparkling spots in fibrocartilage. Sensitivity and specificity appear excellent and possibly better than those of conventional x-rays."[299] Moreover, floating aggregates of crystals can be observed inside fluid collections (see Figure 58-30).

## Septic Arthritis

Septic arthritis is a major emergency in rheumatology. The role of ultrasonography is to provide early findings which can raise the suspicion of joint infection and, potentially, aid in the collection of fluid. Synovial fluid in septic arthritis may show a variable degree of reflectivity. The effusion can range from hyperechoic to hypoechoic, with a diffuse pattern of low-level echoes. Power Doppler signal is generally intense, mostly in periarticular soft tissues. Sonographic-guided aspiration of even minimal collections of synovial fluid may play a key role in early differential diagnosis of acute monoarthritis. Bone and cartilage damage may be detectable in a few days if an aggressive treatment is delayed.

## Osteoarthritis

Ultrasonography is exquisitely sensitive in detecting structural changes of the articular cartilage.[300] Irregularity and/or loss of the thin and sharp contour of the outer border of the hyaline cartilage and/or increased cartilage echogenicity with patchy or diffuse loss of clarity are the earliest ultrasound features of OA. These changes seem to reflect structural alterations, such as fibrillation of cartilage and cleft formation. Variable loss of cartilage is detectable in patients with more advanced disease. Alteration of the subchondral bone, ranging from a tiny irregularity of the bone profile to multiple erosions, can be detected in areas that appear normal on conventional radiography in both erosive and non-erosive OA. A slight increase of cartilage thickness caused by inflammatory edema in the early phases of OA has been described.

Osteophytes are the most frequent and characteristic abnormalities of the bone profile in patients with OA, appearing as irregularities of the bone contour with posterior acoustic shadow. Joint effusions are commonly found in patients with OA. Minimal fluid collections that are not detectable on clinical examination are easily demonstrated by ultrasonography. The inhomogeneous echogenicity of synovial fluid can be related to proteinaceous material, cartilage fragments, aggregates of crystals, and calcified loose bodies. Popliteal cysts are frequent in patients with knee OA. Ultrasonography provides structural details about the content of the cyst, its communication with the joint space, and the possible compression of adjacent vascular structures. Cyst sizes and shapes vary widely, ranging from small (<1 cm) to giant multiloculated formations. Synovial hypertrophy in OA may show sonographic features similar to those observed in patients with RA but without the invasive properties of the rheumatoid pannus. Color/power Doppler ultrasonography is a useful tool to distinguish inflammatory from non-inflammatory knee swelling.[301] It has recently been demonstrated that inflammatory signs are more frequent in erosive osteoarthritis than in nonerosive osteoarthritis, not only in erosive joints but also in nonerosive joints. This finding suggests an underlying systemic cause for erosive evolution.[302]

Ultrasonography-detected capsule distension, synovial inflammation, and effusion are common in painful knee OA and correlate significantly with knee synovitis, effusion, and clinical parameters suggestive of an inflammatory flare. As in RA, ultrasonography detects more joints with inflammation than does clinical assessment. Color/power Doppler ultrasonography is a useful tool to distinguish inflammatory from non-inflammatory knee swelling.[301]

### Diagnosis, Monitoring, and Predicting Outcome

**Diagnosis.** The classification criteria for OA are based on clinical and conventional radiographic findings, not ultrasonography.[48] However, the use of ultrasonography in the diagnosis of OA is favored by the fact that ultrasonography can visualize the pathologic changes described in the preceding text.

**Monitoring.** Ultrasonography can demonstrate changes in synovitis thickness, effusion size, and popliteal cyst size.[303] With respect to structural change, including cartilage damage, the sensitivity to change remains to be determined. Reproducibility data are scarce and no consensus on scoring systems exists. Quantitative assessment of cartilage is restricted to thickness, as total volumes cannot be measured. More work is required to develop standardized definitions of pathology and to demonstrate the validity of ultrasonography in OA.[304]

**Predicting Outcome.** In patients with OA of the hand the presence of ultrasound inflammatory features such as power Doppler signal, synovial thickening and effusions are strongly associated with radiological progression in the subsequent 2 years.[302] Overall, the significance of ultrasonographically detected pathologic conditions in OA with regards to symptoms, prognosis, outcome, and response to therapy remains to be determined.[305]

# OTHER IMAGING MODALITIES

## Digital X-ray Radiogrammetry

**KEY POINTS**

**Digital x-ray radiogrammetry (DXR) performs automated radiogrammetry from conventional hand x-rays and provides an approximated bone mineral density (BMD).**

**Bone loss as measured by DXR-BMD may be useful for monitoring and predicting bone damage in RA.**

Three types of bone loss are early features of RA, focal articular bone erosion, periarticular osteopenia, and systemic osteoporosis. Periarticular bone loss is frequently the earliest radiographic feature of RA and is associated with disease activity and is known to precede bone erosions.[306] Radiographic osteopenia is, however, only detected if there is bone loss greater than 30%.[307]

Digital x-ray radiogrammetry (DXR) is a fully automated technique for performing radiogrammetry from standard hand radiographs to bridge the gap between radiogrammetry and bone densitometry. The DXR technology is based on a combined computerized radiogrammetric and textural analysis of the narrowest parts of the second, third, and fourth metacarpal bones. Based on cortical thickness (cm), porosity index, and an assumption of a constant bone density and elliptical bone, DXR calculates an approximated bone mineral density (BMD; g/cm$^2$).[308] Short-term precision of DXR-BMD (coefficient of variation [CV] and long-term precision have been reported as 0.28% and 0.25%, respectively, and the reproducibility as 0.05% to 0.27%.[309,310]

DXR is highly correlated with periarticular BMD measurements, and can therefore reflect periarticular bone loss even though it measures midshaft cortical bone.[311] DXR-BMD shows greater loss in patients with RA with high levels of inflammation, positive RF, or positive ACPA. Further, measurements of DXR-BMD changes are significantly associated with progression of structural damage in patients with early-stage RA.[312] Losses seen during 1year with DXR-BMD are predictive of subsequent erosive development.[309] However, so far only changes in DXR-BMD have been shown to be of predictive value, limiting its clinical applicability. DXR-BMD changes have also been shown to be responsive to treatment interventions. During disease modifying treatment, DXR-BMD losses are less severe in patients responding to treatment than those who do not.[309,311,312] This suggests that DXR-BMD may become a useful outcome measure and predictor of joint damage in RA clinical trials. However, its clinical usefulness and applicability has yet to be established.

## Nuclear Medicine

**KEY POINTS**

**Nuclear imaging provides not only morphologic but also physiologic information regarding the metabolic state of tissues.**

**Nuclear medicine techniques can be fused with other imaging modalities (e.g., SPECT/CT) providing combined functional and anatomic information.**

**PET can be useful for diagnosis and management of vasculitides, fever of unknown origin, and malignancies.**

**Other imaging modalities are generally better suited than nuclear medicine to investigate inflammatory and degenerative rheumatic diseases in clinical practice**

### Bone Scintigraphy (Planar)

Bone scintigraphy imaging can be planar (i.e., whole body and spot views) or tomographic (i.e., single photon emission tomography [SPECT]). This is analogous to the relationship between planar radiography (conventional x-rays) and CT.

As with all other modalities in diagnostic nuclear medicine, classical bone scintigraphy uses a physiologic/functional approach to imaging bone or joint pathology. By this method, an organic analogue of phosphate (methylene diphosphonate [MDP]) is tagged with a standard radionuclide ($^{99m}$Tc). The combined tracer, $^{99m}$Tc-MDP, is then administered intravenously. This organic phosphate analogue is then distributed with a whole-body distribution proportional to regional perfusion. It is adsorbed onto the surface of osteoid, at the sites of active mineralization (calcium phosphate formation). Throughout the entire diagnostic imaging test, from the onset of tracer administration to the final delayed images (from 3 to 24 hours), nuclear medicine gamma cameras detect photons emitted by the decaying radionuclide, forming diagnostic whole-body or spot images which demonstrate the concentration of the administered tracer. In the first few minutes after administration, the tracer distribution is a reflection of regional perfusion and relative blood pool distribution. By 3 hours, tracer distribution represents true incorporation into osteoid, reflecting local osteoblastic bone metabolism. Tracer which is not incorporated into bone is eliminated by renal excretion. Residual free tracer within plasma and extra-cellular space is proportional to blood pool and soft tissue distribution. At 24 hours, further clearance of physiologic tracer distribution (both bone and soft tissue) amplifies retention of tracer from pathologic accumulation. Radionuclide decay of $^{99m}$Tc (6-hour half-life) precludes any further imaging beyond 24 hours. Effectively, the delayed bone images (3 to 24 hours) provide an indirect measure of osteoblastic activity. Bone scintigraphy provides an imaging map of active bone metabolism.[313,314] Diagnostically, bone scintigraphy allows an opportunity to detect a pathologic condition that is associated with abnormal bone metabolism: specifically, where there is increased (or possibly decreased) osteoblastic activity. In theory, most bone and joint pathologies are associated with some degree of abnormal osteoblastic activity, even those which are primarily destructive or lytic. The sensitivity is limited by the volume of pathologic tissue, the relative intensity of the bone reaction, and physical constraints of photon detection which limit the spatial resolution.

Traditionally, bone scintigraphy has been used to diagnose and characterize a variety of bone and joint pathologies (traumatic, inflammatory, neoplastic, metabolic) (Figure 58-31), particularly in the setting of negative plain radiographs. It has relatively high sensitivity in this regard.[315] Although many traditional uses for bone scintigraphy have been supplanted by anatomic modalities with greater spatial

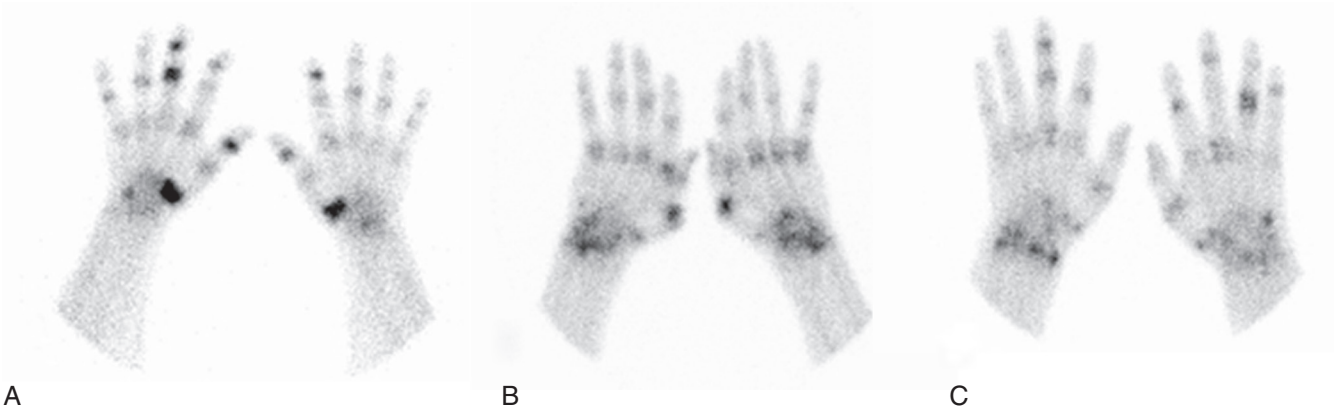

**Figure 58-31 Distributions of activity in osteoarthritis (OA), rheumatoid arthritis (RA) and psoriatic arthritis (PsA), on planar bone scintigraphy.** **A,** *Primary OA.* Severe activity is seen in the first carpometacarpal joint bilaterally and in several proximal interphalangeal (PIP) and distal interphalangeal (DIP) joints. Mild/moderate activity is seen in the index DIP and thumb IP joints bilaterally. **B,** *RA.* Symmetric activity is seen in the radiocarpal joints, and all MCP and PIP joints. **C,** *PsA.* Bilateral asymmetric distribution is seen, in the right radiocarpal and in bilateral PIP and DIP in different fingers. Note the ray distribution in the right third finger.

resolution such as MRI and CT, scintigraphy is still the imaging modality of choice for certain specific clinical problems (e.g., follow-up of osteoblastic bone metastases, diagnosis of shin splints, demonstration of reflex sympathetic dystrophy). Bone scintigraphy is complementary to anatomic modalities such as CT and MRI because it provides an alternate, functional view of bone pathology that may not be anatomically apparent.

Whole body bone scintigraphic images are still the most efficient means of observing systemic bone pathology such as widespread bony metastatic disease, metabolic bone disease, or bone marrow expansion. A traditional three-phase planar bone scan is also efficient at demonstrating certain regional pathologies.[316]

From a rheumatology perspective, bone scintigraphy can demonstrate evidence of active arthritis (see Figure 58-31).[317] The whole-body surveillance capability easily documents the specific distribution of an active systemic arthritis or other concurrent systemic pathology. This information can augment or complement a clinical rheumatologic impression. In the presence of anatomically established arthropathy, bone scintigraphy can distinguish a metabolically active from an inactive joint.[318] From an orthopedic standpoint, bone scintigraphy has the ability to demonstrate bone stress reactions, periosteal reactions, or fractures. This is sometimes valuable for orthopedic surgical management.[319] In the evaluation of arthritides, scintigraphy can be a useful adjunct to clinical assessment, but should not be used routinely. Bone scans are more sensitive than conventional radiographs for detecting active bone pathology, but MRI is usually more sensitive and specific than bone scintigraphy, with the added advantage of not using ionizing radiation.[260,320,321] However, bone scintigraphy can provide a useful complementary role to MRI and other modalities for several clinical situations.

In addition to the use of ionizing radiation, costs, and limited spatial resolution, traditional planar bone scans have limited anatomic resolution, depending on the body part. Because the location of active pathology is often as important as its presence, this limitation has often reduced the specificity and overall accuracy of traditional planar bone scans.

### Single-Photon Emission Computer Tomography with and without Computed Tomography

SPECT (single-photon emission tomography) is the generation of cross-sectional scintigraphic images by processing multiple planar images obtained over a large range of camera positioning relative to the patient. The relationship of SPECT to planar scintigraphic imaging is analogous to the relationship between CT and plain radiography. Tomographic bone scintigraphy imaging provides improved sensitivity for the detection of pathologies such as active facet arthritis or spondylolysis.[322] However, precise anatomic location of the active pathology seen on conventional SPECT images (i.e., without concurrent CT), can be very difficult. This reduces its specificity. For example, facet arthritis versus active spondylolysis or other pathology in the posterior elements of a vertebral segment may be difficult to distinguish on SPECT imaging alone.

SPECT/CT is an example of modern fusion imaging. Other examples include positron emission tomography (PET)/CT and PET/MRI (see subsequent text). SPECT/CT is the acquisition of a CT study concurrent with the acquisition of a nuclear medicine SPECT study, while the patient remains in the same body position. This is performed by a single machine: a SPECT/CT capable gamma camera. The high resolution, anatomically specific CT images are then fused with the functional images from SPECT. The combined, fused images appear to provide far greater diagnostic accuracy than either alone. It is an effective marriage of tomographic imaging between functional (SPECT) and anatomic (CT) images.

SPECT/CT has, as PET/CT, revolutionized nuclear medicine imaging. The traditional weakness of nuclear medicine imaging, lack of anatomic resolution, has been largely corrected by its fusion with CT. In addition to identifying a functionally active abnormality, SPECT/CT now allows its precise anatomic localization to the extent allowed by

modern CT. The effect of this anatomic precision is a dramatic increase in the anatomic and overall diagnostic specificity of bone scintigraphy (and all other nuclear medicine modalities) when augmented with SPECT/CT. This improved specificity has been demonstrated for multiple medical problems such as infection, trauma, and tumor imaging.[323,324]

There is an approximate congruence between bone marrow edema seen on MRI and low to medium-grade patches of bone reaction.[325,326] As a result, fused bone SPECT/CT images approach the diagnostic capabilities of MRI in certain situations. Specific soft tissue pathologies, which are not traditionally diagnosed with bone scintigraphy (e.g., severe tendinopathy [Figure 58-32], subtle enthesitis, ligamentous injuries) can now be suggested by adjacent bone reaction combined with soft tissue findings on CT.

To assess arthropathy, SPECT/CT can occasionally diagnose a specific arthritis by the combination of an appropriate distribution of metabolically active arthropathy and specific anatomic findings on CT (Figures 58-33 and 58-34). When SPECT/CT, as CT, is used in clinical practice, the radiation dose should be considered.

The current literature for SPECT/CT imaging is deficient, with a significant lag behind technological advancement. Multiple musculoskeletal pathologies now visible on bone SPECT/CT which were previously visible only with conventional anatomic imaging (CT and MRI) have not yet been adequately documented in the nuclear medicine imaging literature. Multiple new signs and patterns of bone reaction which can offer indirect diagnoses of soft tissue pathologies have yet to be documented and fully assessed with respect to the sensitivity and specificity of their detection by bone SPECT/CT imaging. Furthermore, many current practicing interpreters of bone scintigraphy may need further education and experience with diagnostic CT for musculoskeletal pathology. Therefore, the full diagnostic capability of bone scintigraphy with SPECT/CT is not optimally used in current practice.

SPECT/MRI, another fusion imaging modality, is a theoretical possibility, but the potential utility of such an imaging modality has yet to be defined.

Various other tracers besides $^{99m}$Tc-MDP are available to detect inflammatory pathologies. Options include $^{67}$Ga citrate scan, $^{111}$In white blood cell (WBC) scan, $^{99m}$Tc WBC scan with or without concurrent bone marrow imaging (Figure 58-35), and $^{18}$F-fluorodeoxyglucose ($^{18}$FDG)-PET.[315,327] These may assist with imaging workup of osteomyelitis or soft tissue infection.

Similar to planar bone scintigraphy, SPECT/CT technology can be used for each nuclear medicine tracer,

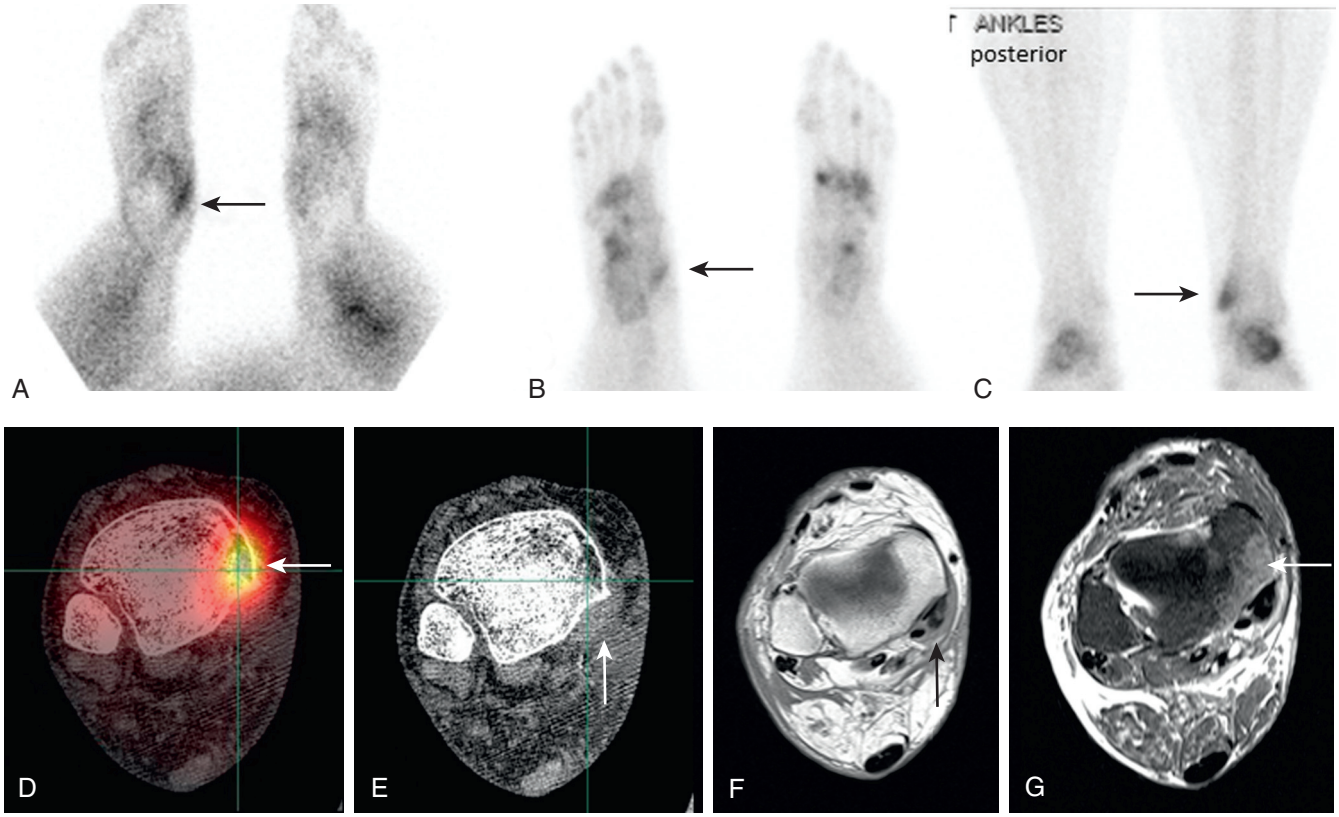

**Figure 58-32 Tibialis posterior tendinopathy demonstrated by bone single photon emission tomography/computed tomography (SPECT/CT).** A 74-year-old female with chronic pain in the medial malleolus. **A** and **C,** Planar bone scintigraphy. Initial planar blood pool images **(A)** show hyperemia in the vicinity of the right medial malleolus. Delayed bone images (**B** and **C**) show low grade bone reaction within the medial malleolus. **D,** SPECT/CT confirms the presence of a bone reaction in the medial malleolus *(arrow)*. **E,** The CT component of SPECT/CT demonstrates a thickened tibialis posterior tendon with abnormal contour *(arrow),* suggesting severe tendinopathy with an adjacent bone reaction. **F** and **G,** MRI confirms these findings because a proton density-weighted axial MR image **(F)** shows a longitudinal split tear and tenosynovitis of the tibialis posterior tendon (*arrow* in **F**), and the corresponding short tau inversion recovery MR image **(G)** with reactive bone marrow edema in the adjacent medial malleolus (*arrow* in **G**).

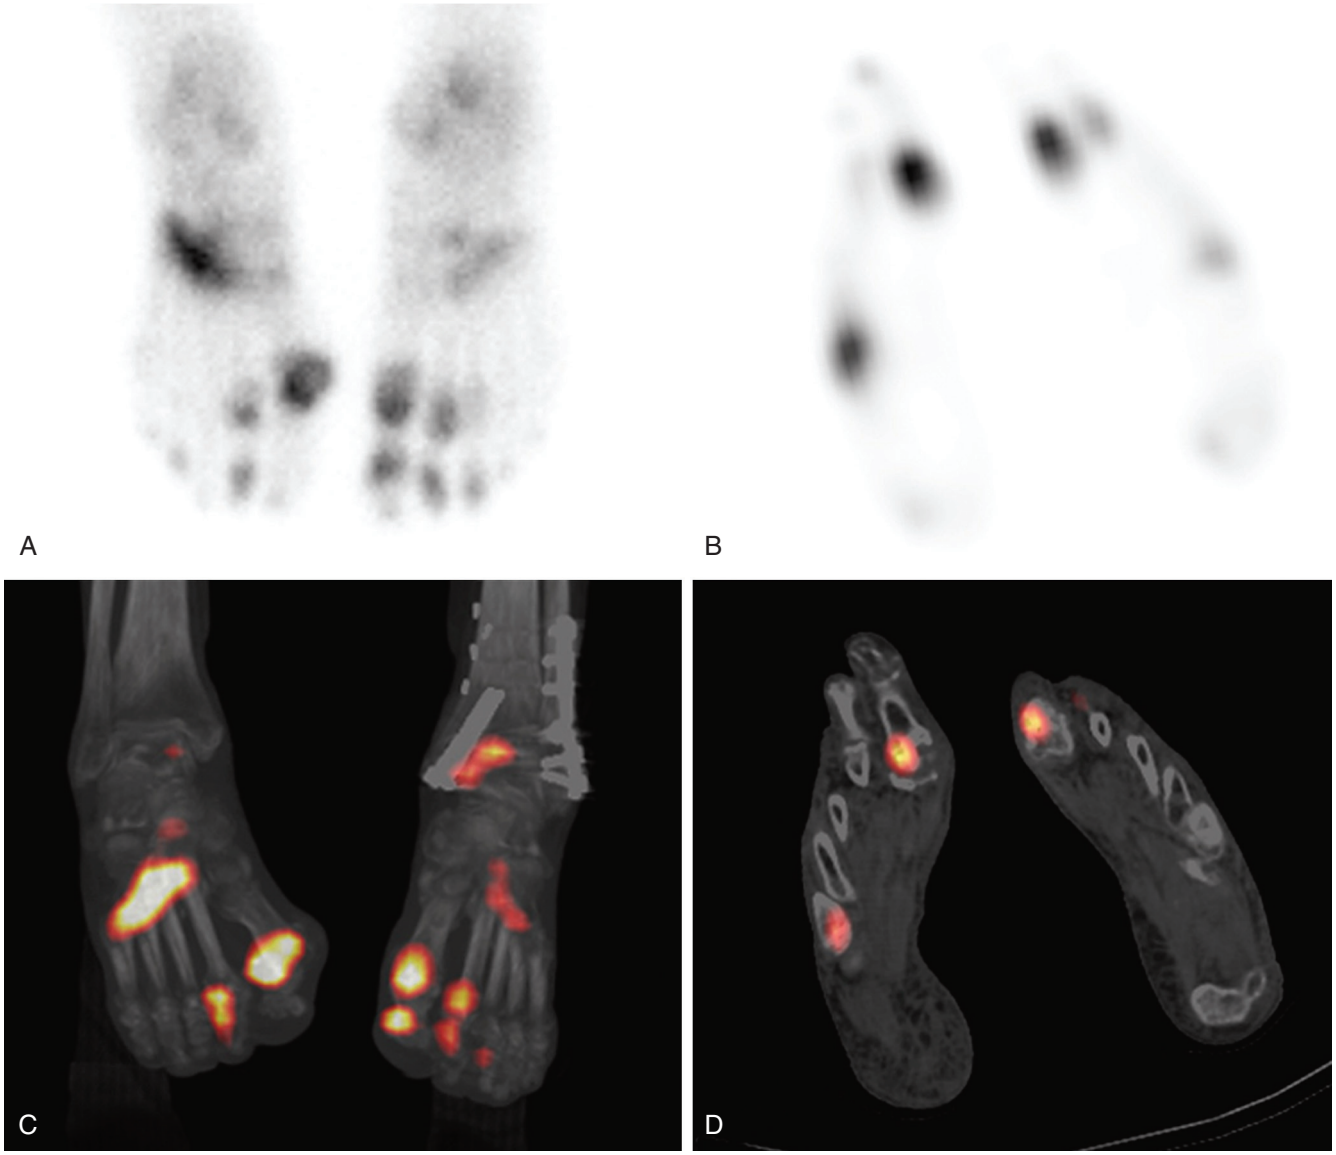

**Figure 58-33 Gout (single-photon emission computed tomography [SPECT]).** A 72-year-old female patient with known gout and prior trauma was investigated for possible complications. Planar **(A)** and transverse SPECT **(B)** images show multifocal increased uptake. Three-dimensional fused SPECT-CT **(C)** and transverse two-dimensional SPECT-CT **(D)** images provide superior localization of scintigraphic activity corresponding to the joints most affected by gout.

providing the same degree of improved anatomic and diagnostic specificity.

The choice of imaging agent depends on the specific clinical scenario: native versus violated bone, axial versus peripheral skeleton, prosthetic infection, acute versus chronic infection, fever of unknown origin. A discussion of optimal inflammatory imaging for each clinical condition is beyond the scope of this discussion.

## Positron Emission Tomography

PET is a functional imaging technique that enables metabolic mapping of tissues in vivo with positron-emitting radionuclides. $^{18}$FDG is the most commonly used radiopharmaceutical in PET because of its availability, favorable 110-minute half-life, and high uptake in most metabolically active tissues. When injected into the body, $^{18}$FDG demonstrates sites of increased glucose metabolism, thus identifying sites of metabolically active pathology in both bone and soft tissue. The metabolically active pathology can be malignant, inflammatory, or infectious. A PET scan is inherently tomographic and has a slightly higher spatial resolution than a SPECT scan. A PET/CT scan acquires both a PET and CT scan concurrently on the same machine, allowing for fusion of the two sets of images. Similar to SPECT/CT, the CT component of PET/CT provides a precise anatomic map which is fused with the functional images of glucose metabolism provided by PET.

$^{18}$FDG PET/CT is most often used in oncology, in which it has a well-established role for the diagnosis and clinical management of several malignancies. But $^{18}$FDG PET/CT imaging is also useful for a variety of clinical problems in cardiology, neurology, and infectious diseases. For example,

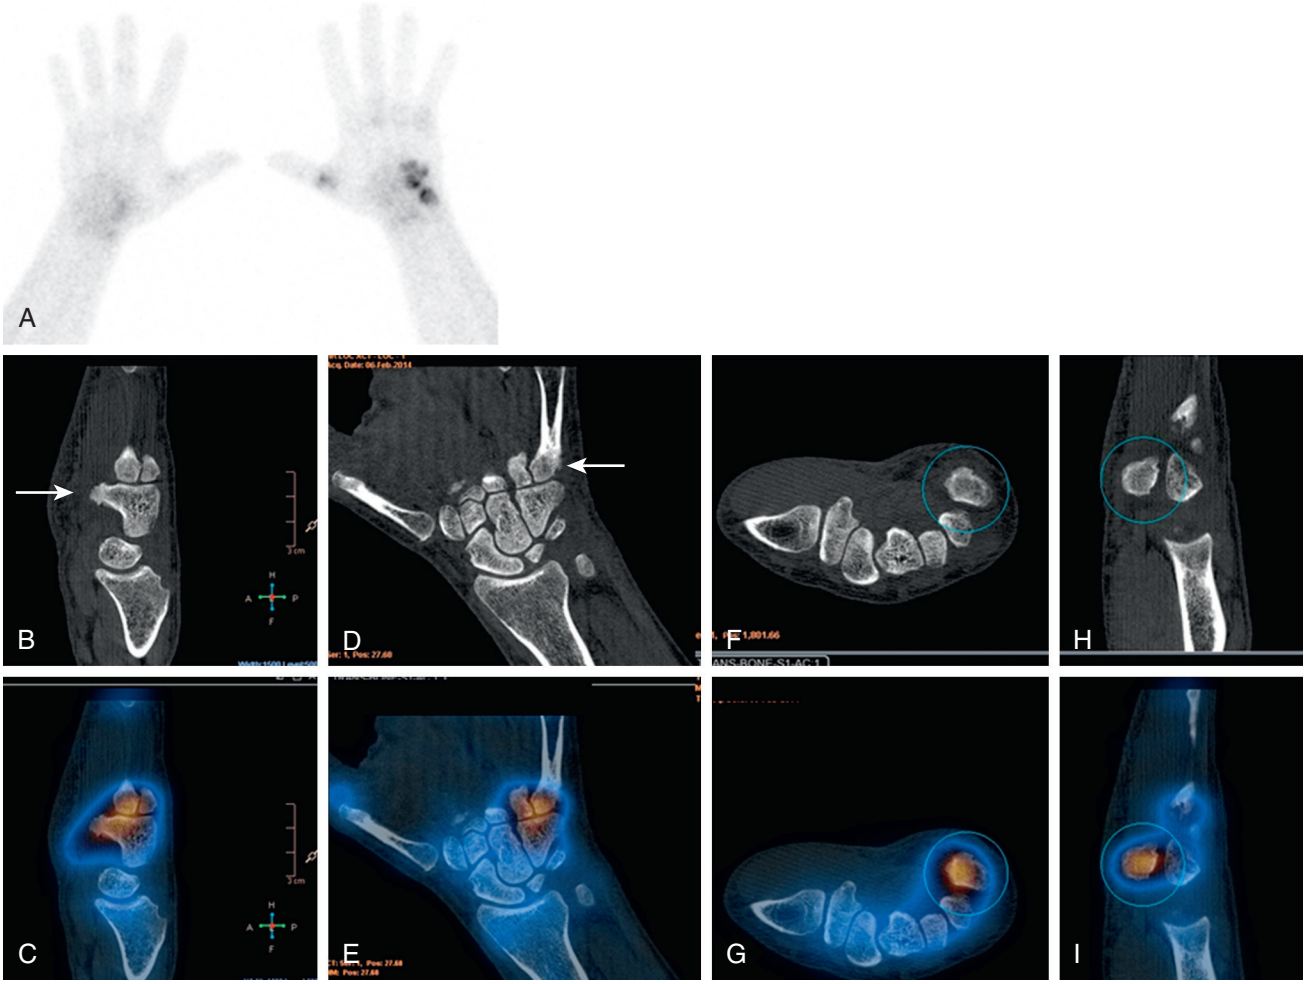

**Figure 58-34 Radiographically occult seronegative arthritis on single-photon emission tomography/computed tomography (SPECT/CT).** A 43-year-old man with pain in hands and feet for years, and normal radiographs. **A,** Planar bone scintigraphy of the hands show a nonspecific pattern of bone reaction within the pisiform and several ulnar-sided carpal bones including the fourth and fifth carpometacarpal (CMC) joints. Planar bone scintigraphy images of the feet (not shown) suggested enthesopathy in the base of the left fifth metatarsal bone and synovitis in the right ankle. **B** through **I,** SPECT/CT demonstrates active arthritis in the fourth and fifth CMC joints **(C, E)** and the pisiform **(G, I)**, with glowing orange signal. Images **B, D, F,** and **H** are CT images in the sagittal **(B, H)**, coronal **(D)** and axial **(F)** planes, and **C, E, G,** and **I** are the corresponding fused SPECT/CT images. Bone reactions on SPECT/CT include the hook of the hamate (*arrow* in **B**), the base of the fifth metacarpal (*arrow* in **D**), and the pisiform at the attachment of flexor carpi ulnaris tendon (*arrow* in **F**), where the CT shows fine, fluffy, whisker-like enthesopathy. The distribution of findings on planar images and on SPECT/CT suggest the presence of a seronegative arthritis, which was subsequently serologically confirmed.

$^{18}$FDG PET is now considered by many to be the diagnostic imaging test of choice to assess fever of unknown origin.[328] $^{18}$FDG PET has the highest overall sensitivity and specificity for the diagnosis of chronic osteomyelitis compared with bone scintigraphy, CT, and MRI.[329]

The uptake of $^{18}$FDG, similar to many other nonspecific inflammatory tracers, can conveniently demonstrate the presence and distribution of systemic disease.[330] In rheumatology, $^{18}$FDG-PET can be useful for the diagnosis and management of large-vessel vasculitis such as Takayasu's arteritis and that associated with granulomatosis with polyangiitis, polyarteritis nodosa, giant cell arteritis, and polymyalgia rheumatic (Figure 58-36).[327,331,332] $^{18}$FDG uptake is strongly correlated with MRI synovitis in RA,[333] but the role, if any, in routine clinical management of inflammatory arthritides remains to be determined.

## CONCLUSION

Imaging is an integral part of management of patients with rheumatic diseases. This chapter has outlined the status of imaging in rheumatic diseases, with a particular focus on inflammatory joint diseases. Please see the key point boxes for main messages. The chapter has explained the important role of conventional radiography, but also the exciting new opportunities to be gained with newer imaging techniques. The last decade has brought a vast amount of new knowledge that has dramatically changed the way we manage our patients with rheumatic diseases. It is exciting that with continued dedicated research and the rapid technical development it is likely that even larger improvements may occur in the decade to come, for the benefit of our patients.

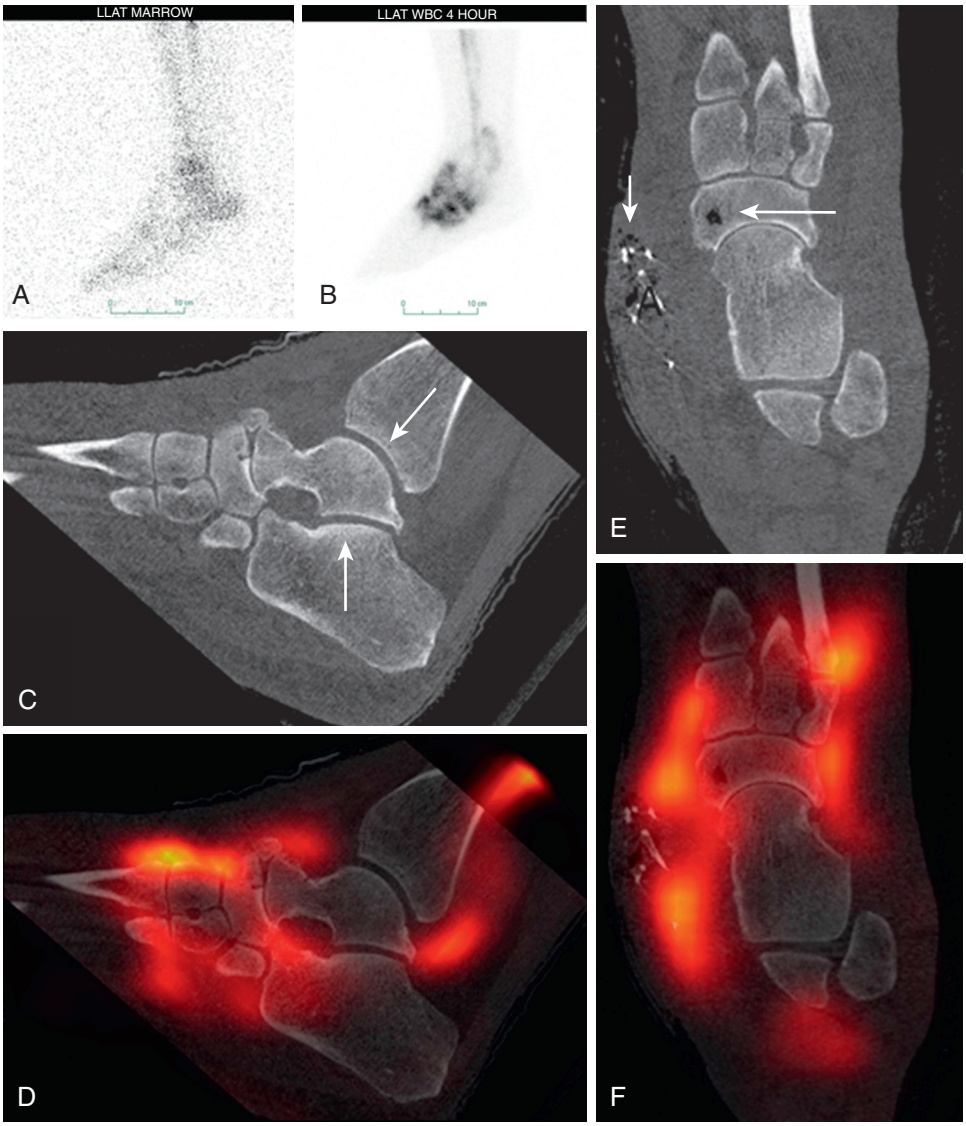

**Figure 58-35 Extensive septic arthritis of the midfoot demonstrated by planar white blood cell (WBC) bone scintigraphy and with single photon emission tomography/computed tomography (SPECT/CT).** A 41-year old male with soft tissue infection after minor surgery for removal of a small skin lesion in the dorsal/medial aspect of the midfoot. Extensive cellulitis was apparent clinically, along with a soft tissue abscess which was surgically drained. Standard planar bone marrow image, by using 99m technetium-sulfur colloid tracer **(A),** and WBC **(B)** image show intense, extensive WBC activity throughout the entire midfoot, with a bone and joint (rather than superficial soft tissue) distribution **(B)**. This is grossly incongruous with the distribution of bone marrow **(A),** suggesting that the WBC distribution represents extensive septic arthritis. **C** through **F,** Sagittal **(C)** and axial **(E)** CT and the corresponding SPECT/CT images **(D, F)** (i.e., CT fused with WBC SPECT). SPECT/CT confirms deep midfoot infection, with septic arthritis and osteomyelitis. WBC activity (**D** and **F**) has an articular (faint), periarticular and deep soft tissue distribution. The CT **(E)** shows medial soft tissue gas and speckled high density *(short arrow)* in the site of surgical débridement. Intraosseous gas in the navicular (*long arrow* in **E**) demonstrates at least one site of contiguous osteomyelitis. WBC uptake is seen within most joints of the midfoot (**D** and **F**). Note the sparing of the ankle and posterior subtalar joints (*thin arrows* in **C**), because they do not anatomically communicate with the midfoot joints.

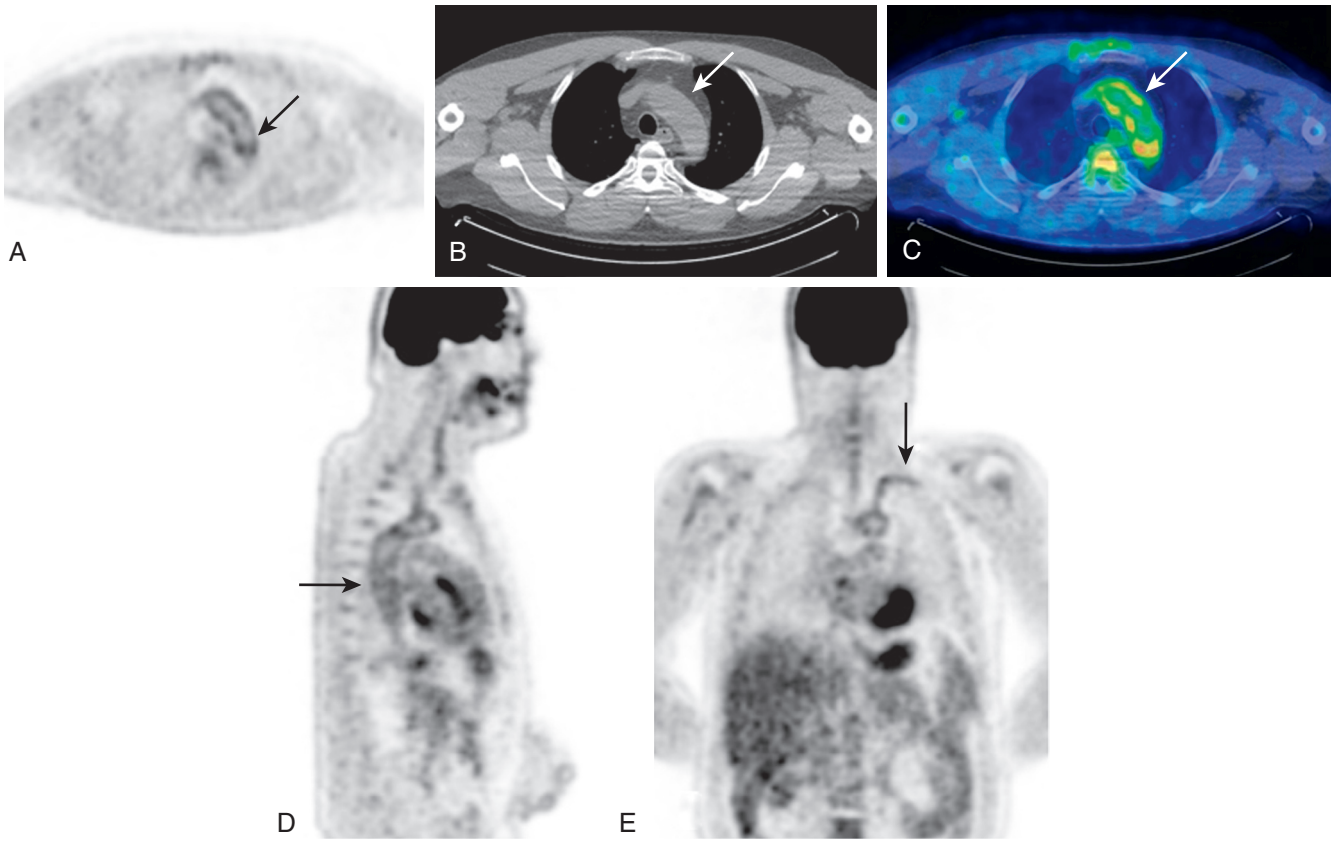

**Figure 58-36 Takayasu's arteritis, visualized by positron emission tomography/computed tomography (PET/CT).** A 46-year-old male with Takayasu arteritis receiving glucocorticoid therapy. An $^{18}$F-fluorodeoxyglucose PET/CT scan was requested to document active vasculitis because suboptimal therapy was suspected. **A** through **E,** Axial PET **(A),** CT **(B),** PET/CT **(C),** and sagittal **(D)** and coronal **(E)** PET images. Moderately intense inflammation is present in the aortic arch (**A, B,** and **C**) and descending aorta (*arrow* in **D**). Inflammation extends to the great vessels, including the left subclavian artery (*arrow* in **F**). These suggest persistent, active vasculitis.

PART 8 PHARMACOLOGY OF ANTI-RHEUMATIC DRUGS

CHAPTER 59

# Biology and Therapeutic Targeting of Prostanoids

Leslie J. Crofford

**KEY POINTS**

- NSAIDs are effective anti-inflammatory, antipyretic, and analgesic compounds.
- There is little difference in the efficacy of the various NSAIDs, but the pharmacologic characteristics of individual drugs, including potency, half-life, and relative inhibition of cyclooxygenase (COX)-1 and COX-2, play important roles in toxicity.
- Aspirin is an NSAID used in low doses to prevent cardiovascular disease. Taking aspirin and NSAIDs together is associated with increased toxicity in the gastrointestinal (GI) tract, and concomitant use of some NSAIDs with aspirin may be associated with aspirin resistance.
- NSAIDs are associated with risk for GI ulceration and bleeding. Patient-specific risk factors for toxicity should be recognized so risk-reduction strategies can be implemented.
- NSAIDs are associated with an elevated risk for cardiovascular disease. Clinicians should be aware of cardiovascular risk factors and either avoid prescribing NSAIDs or use intermittent dosing, low doses, or drugs with a short half-life.
- Periodic assessment of blood pressure, hemoglobin, electrolytes, renal function, and liver function is advisable, particularly in elderly patients.

The use of NSAIDs is ubiquitous in the practice of medicine because of their effectiveness as anti-inflammatory, analgesic, and antipyretic agents. NSAIDs differ widely in their chemical class but share the property of blocking production of prostaglandins (PGs). This effect is accomplished by inhibiting the activity of the enzyme PG G/H synthase (PGHS), also called *cyclooxygenase* (COX).

The clinical effects of NSAIDs are evaluated not only by their specific pharmacologic properties but also in terms of their effects on the different COX isoforms, COX-1 and COX-2. These isoforms serve different biologic functions in that COX-1 is expressed under basal conditions and is involved in the biosynthesis of PGs that serve homeostatic functions, whereas COX-2 expression is increased during inflammation and other pathologic situations. Inhibition of COX-2 by NSAIDs blocks PG production at sites of inflammation, whereas inhibition of COX-1 in certain other tissues, most importantly platelets and the gastroduodenal mucosa, can lead to common adverse effects of NSAIDs such as bleeding, bruising, and gastrointestinal (GI) ulceration.

In addition to their use in people with rheumatoid arthritis (RA) and osteoarthritis, NSAIDs are widely used in the symptomatic management of other rheumatic diseases characterized by chronic musculoskeletal pain and diverse forms of acute pain. Aspirin, which has unique properties among NSAIDs, is used by millions of people for primary and secondary prevention of cardiovascular thrombosis. In light of the widespread use of these drugs for common diseases, which are likely to increase in prevalence with the aging of the population, it is critically important to appreciate the potential adverse events and drug interactions associated with NSAIDs.

This chapter analyzes aspirin and other NSAIDs on the basis of their chemical structure, pharmacologic properties, and relative inhibition of COX-1 and COX-2. Particular attention to potential adverse events of specific NSAIDs in individual patients will facilitate use of these drugs in the safest possible manner. Acetaminophen (known as *paracetamol* outside the United States), an antipyretic and analgesic drug without anti-inflammatory activity, inhibits COX enzymes via a different mechanism than NSAIDs and is also discussed. Colchicine possesses anti-inflammatory characteristics similar to NSAIDs in some situations and is discussed in this chapter, although this drug differs in its mechanism of action and profile of adverse effects.

## HISTORY

Botanicals containing salicylates have been used since antiquity to treat pain, inflammation, and fever. About 3500 years ago, the Egyptian Ebers Papyrus recommended use of a decoction of dried myrtle leaves to be applied to the abdomen and back for relief of rheumatic pains. A thousand years later, Hippocrates recommended poplar tree juices for treatment of eye disease and willow bark to alleviate fever and the pain of childbirth. Throughout Roman times, the use of botanical treatments, including willow bark for pain and inflammation, was widespread. Plants containing salicylate were used medicinally in China and other parts of Asia. In addition, the curative effects of other botanicals were known to the indigenous populations of North America. Extracts of the autumn crocus plant

containing colchicine were used for treatment of acute gout as early as the sixth century AD.[1]

The first modern description of the therapeutic application of plants containing salicylates was reported to the Royal Society of London by the Reverend Edward Stone, who provided an account of the successful use of dried willow bark for fever.[1] In this first "clinical trial," a pound of bark was dried, pulverized, and put into the tea, beer, or water of 50 people with fever. Stone found that one dose (1 dram = 1.8 g) cured their fever. In 1763, Stone wrote, "I have no other motives for publishing this valuable specific, than that it may have a fair and full trial in all its variety of circumstances and situations, and that the world may reap the benefits accruing from it."

In 1860 salicylic acid was chemically synthesized, which led to its widespread use as an external antiseptic, antipyretic, and analgesic.[1] The bitter taste of salicylic acid prompted the chemist Felix Hoffman to synthesize the more palatable acetylsalicylic acid (ASA). After a demonstration of its anti-inflammatory effects, Dr. Heinrich Dreser of Bayer introduced this compound into medicine in 1899 as aspirin, and it remains the most widely used drug in the world.[1] Salicylate was identified as the active ingredient of willow bark in 1929.

Phenylbutazone came into clinical practice in 1949 and was followed by indomethacin, fenamates, naproxen, and others. Despite the diversity of their chemical structures, these drugs shared therapeutic properties with aspirin. Furthermore, adverse events including gastric upset, GI ulceration and bleeding, hypertension, edema, and renal damage were shared by all these drugs. In 1971 it was discovered that these drugs all acted by inhibiting PG biosynthesis, thereby providing a unifying explanation of their therapeutic actions and a rationale for grouping them together as NSAIDs.[1]

COX was isolated in 1976 from the endoplasmic reticulum of PG-forming cells.[2,3] However, several groups of investigators speculated that there must be a second COX enzyme on the basis of observed biology. In 1990, investigators demonstrated that bacterial lipopolysaccharide (LPS) increased PG synthesis in human monocytes in vitro and in mouse peritoneal macrophages in vivo, but only the LPS-induced increase was inhibited by dexamethasone and required the de novo synthesis of "new" COX protein.[4] This observation was the foundation of the concept for "constitutive" and "inducible" forms of COX. Soon thereafter, a number of investigators working in different systems reported the discovery of an inducible second form of COX.[3] Investigators who proceeded to clone the gene and deduced its structure found that the gene product was homologous to COX but to no other known protein. The observation that glucocorticoids inhibited the expression of COX-2 after a pro-inflammatory stimulus represented a link between the anti-inflammatory actions of NSAIDs and corticosteroids.

Because of the prediction that inhibition of COX-2 would block PG biosynthesis participating in the inflammatory response but was not required for homeostasis, there was a tremendous effort to develop drugs that selectively inhibit COX-2 without effect on COX-1 in the belief that these medications would provide clinical efficacy without adverse effects.[2,5] Identification of new drugs that differentially inhibited COX-2 over COX-1 was accomplished quickly as existing NSAIDs were tested on the two COX isoforms and crystal structures revealed differences in the protein structures on which new drug development could be based.[5,6]

One hundred years after aspirin was introduced and 10 years after the discovery of COX-2, the selective COX-2 inhibitors, celecoxib and rofecoxib, were developed. In clinical trials, the safety and efficacy profiles of these and related drugs showed promise, and the U.S. Food and Drug Administration (FDA) subsequently approved these COX-2–selective NSAIDs for treatment of arthritis and pain. After their introduction into clinical practice, however, it became clear that the most highly COX-2–selective NSAIDs, particularly rofecoxib, were more likely than traditional NSAIDs to be associated with adverse cardiovascular events.[7] This finding led to the voluntary withdrawal of rofecoxib and several other COX-2–selective NSAIDs from the market. Debate surrounding the relative risks of different NSAIDs to specific organ systems continues to the present day.

## CYCLOOXYGENASE BIOLOGY AND BIOACTIVE LIPIDS

Therapeutic and adverse effects of NSAIDs are best understood in the context of COX biology. The COX enzymes are the first committed step in the synthesis of PG from arachidonic acid (AA; Figure 59-1). AA is an omega-6 polyunsaturated fatty acid (PUFA) commonly found at the *sn*-2 position of cell membrane glycerophospholipids and cleaved from cell membranes by one of several different phospholipase $A_2$ enzymes.[8] Once generated, AA may enter several different pathways to generate bioactive lipids. It can be metabolized by COX to $PGG_2$ and then $PGH_2$ via its COX and peroxidase enzyme activities; by lipoxygenases (LOX) to hydroxyeicosatetraenoic acids (HETEs), hydroperoxyeicosatetraenoic acids (HPETEs), or leukotrienes; or by the cytochrome P450 family of enzymes to HETEs, HPETEs, or epoxyeicosatrienoic acids (EETs).[9,10] These bioactive lipids have diverse biologic activities in normal physiology and in pathologic conditions, including inflammation, pain, cardiovascular disease, and cancer.

In the COX pathway, the unstable intermediate $PGH_2$ spontaneously rearranges or is enzymatically converted by specific synthases to biologically active PG, of which there are many isoforms.[3] Although phospholipase $A_2$ activity is required to initiate PG synthesis, the overall regulation of the type and amount of PG produced in a given cell or tissue is determined by the expression levels of COX-1, COX-2, and terminal synthase enzymes.

Bioactive lipids synthesized via the COX and LOX pathways are important mediators of inflammation, but alternative substrates and pathways can generate anti-inflammatory lipids and lipids important in the resolution of inflammation (Figure 59-2).[11,12] Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), which are omega-3 PUFAs, can also serve as substrates for COX and LOX, and their metabolic pathways lead to generation of resolvins, protectins, and maresins, which are bioactive lipids associated with resolution of inflammation.[12,13] It is hypothesized that generation of anti-inflammatory lipids and lipids that accelerate

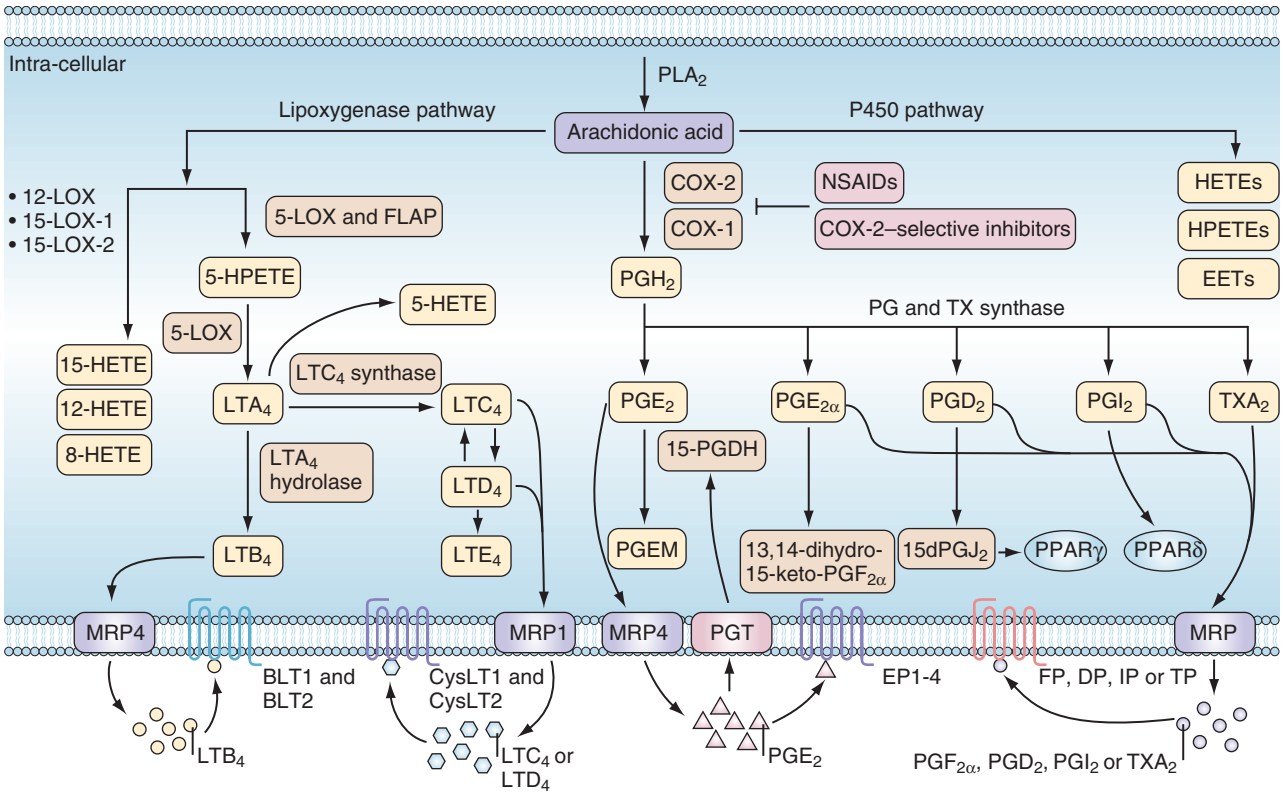

**Figure 59-1** An overview of human eicosanoid synthesis pathways. Arachidonic acid (AA) is a polyunsaturated fatty acid that constitutes the phospholipid domain of most cell membranes and is liberated from the cellular membranes by cytoplasmic phospholipase $A_2$ ($PLA_2$). Free AA can be metabolized to eicosanoids through three major pathways: the cyclooxygenase (COX), lipoxygenase (LOX), and cytochrome P450 monooxygenase pathways. In the COX pathway, the key step is the enzymatic conversion of AA to the intermediate prostaglandin $G_2$ ($PGG_2$), which is then reduced to an intermediate $PGH_2$ by the peroxidase activity of COX. $PGH_2$ is subsequently metabolized to prostanoids, including PGs and thromboxanes (TX), by specific synthases. LOX converts AA to biologically active metabolites such as leukotrienes (LTs) and hydroxyeicosatetraenoic acids (HETEs). P450 metabolizes AA to epoxyeicosatrienoic acids (EETs). In the 5-LOX pathway, AA is converted to an intermediary 5-hydroperoxyeicosatetraenoic acid (5-HPETE), which is converted to $LTA_4$. $LTA_4$ is subsequently converted to 5-HETE, $LTB_4$, $LTC_4$, $LTD_4$, and $LTE_4$. Each of the PGs and LTs exerts its biologic effects by binding to its cognate G protein–coupled receptor. $PGI_2$ can transactivate the nuclear peroxisome proliferator-activated receptor δ (PPARδ), and a $PGD_2$ dehydration product, $15dPGJ_2$, is a natural ligand for PPARδ. The multidrug resistance–associated protein (MRP) gene family is composed of efflux transporters for both PG and LT. PG transporter (PGT) is an influx transporter for PG. Hydroxyprostaglandin dehydrogenase 15-(NAD) (15-PGDH) mainly metabolizes intra-cellular $PGE_2$ and $PGF_{2\alpha}$ to stable 13,14-dihydro-15-keto-PGs. BLT, Leukotriene B(4) receptor; CysLT, cysteinyl leukotriene; DP, prostaglandin $D_2$ receptor; FLAP, 5-lipoxygenase-activating protein; FP, prostaglandin F receptor; IP, prostacyclin receptor; PGEM, prostaglandin $E_2$ metabolite; PGT, prostaglandin transporter; TP, thromboxane $A_2$ receptor. *(From Wang D, Dubois RN: Eicosanoids and cancer.* Nat Rev Cancer *10:181–193, 2010.)*

resolution of inflammation may explain why diets high in omega-3 fatty acids are associated with reduced inflammatory and cardiovascular diseases.[11] In addition, ASA possesses the capacity to alter COX-2 activity such that an "ASA-triggered" alternative catalytic cascade also results in synthesis of anti-inflammatory products, including lipoxins, protectins, and resolvins (see Figure 59-2).[11]

## Prostaglandin Production and Action

PGs act as autocrine and paracrine mediators with effects limited to the immediate vicinity of their synthesis. That PG actions are limited to their site of synthesis reflects their ephemeral nature and predisposition to metabolic inactivation to regulate promptly their potent biologic activities. Thus the enzymes required for production of a specific prostanoid must be co-localized and adjacent to the receptor mediating the action of prostanoids. Most cell types produce only one or a few prostanoid species; however, transcellular metabolism of unstable intermediates of COX may mediate qualitative and quantitative changes in the profile of eicosanoids produced in a given tissue.[14] PGs are exported from cells via the multidrug resistance–associated protein family of efflux transporters, and the PG transporter mediates influx of PG and metabolism to stable products via hydroxyprostaglandin dehydrogenase (see Figure 59-1).[10]

$PGE_2$, the most abundant PG at sites of inflammation, can be produced by many different cell types via at least three different PGE synthases.[15] Expression of the inducible form of PGE synthase, microsomal PGE synthase 1 (mPGES-1), is similar to expression of COX-2. mPGES-1 acts in concert with COX-2 to produce high levels of $PGE_2$ during inflammation. mPGES-1 expression is blocked by NSAIDs, and experiments demonstrate that $PGE_2$ itself, along with pro-inflammatory stimuli, is required for mPGES-1 upregulation.[16] This positive regulatory loop contributes to the high levels of $PGE_2$ at sites of inflammation and likely to the efficacy of NSAIDs. Other terminal PG synthases are not known to be highly regulated, and levels of other important bioactive PGs are stably produced or their levels are increased when phospholipase activity and COX-2 levels are increased.

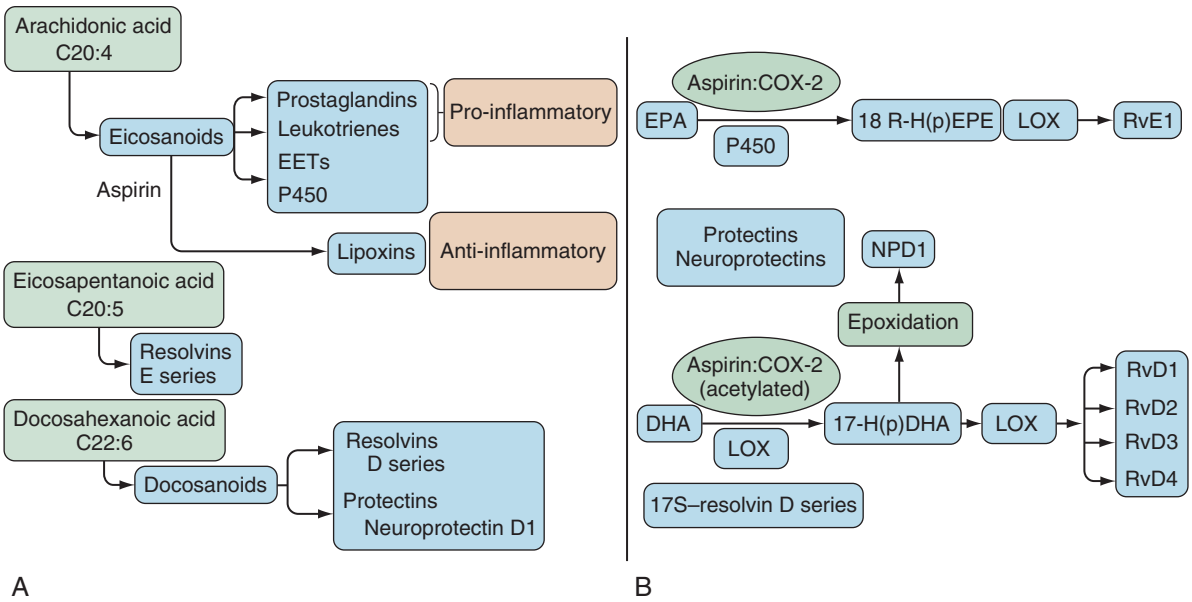

**Figure 59-2** Biosynthesis of anti-inflammatory lipids. Function of essential polyunsaturated fatty acids in the production of families of bioactive lipid mediators. **A,** Arachidonic acid is the precursor of metabolites that function as pro-inflammatory mediators. Prostaglandins and leukotrienes play pivotal roles in the progression of inflammation. Through cell-cell interactions, exemplified by platelet leukocytes in the vasculature or polymorphonuclear cell–mucosa interactions, or both, lipoxins are generated. They serve as "stop signals" and promote resolution. They also serve as endogenous anti-inflammatory mediators self-limiting the course of inflammation. The essential omega-3 fatty acids eicosapentaenoic acid and docosahexaenoic acid (C20:5 and C22:6) are converted to new families of lipid mediators that are pivotal in promoting resolution (as in **B**). Resolvins of the E series such as RvE1 are generated from eicosapentaenoic acid, and resolvins of the D series such as RvD1 and the protectins such as neuroprotectin D1 (NPD1) are generated from docosahexaenoic acid, for which neural systems are enriched. **B,** Aspirin affects the formation of resolvin E1 by acetylating cyclooxygenase (COX)-2 in vascular endothelial cells, which, in a "stereoselective" way, can generate 18 R-H(p)EPE (hydroperoxyeicosapentaenoic acid), which is picked up through transcellular metabolism by leukocytes and converted by a lipoxygenase (LOX)-like mechanism to resolvin E1. Aspirin also affects the formation of D-series resolvins and catalytically switches COX-2 to a 17 R-LOX–like mechanism that serves to generate 17 R-series resolvin D. Aspirin also affects the formation of protectins and neuroprotectins by a similar mechanism and generates compounds carrying the 17 R epimer at the alcohol at carbon-17 in neuroprotectin D1 and other protectins. DHA, Docosahexaenoic acid; EET, epoxyeicosatrienoic acid; EPA, eicosapentaenoic acid; H(p)DHA, hydroperoxydocosahexaenoic acid. *(Modified from Serhan CN, Savill J: Resolution of inflammation: the beginning programs the end.* Nat Immunol *6:1191–1197, 2005.)*

The actions of PG are mediated by cell surface G protein–coupled receptors (GPCRs). At least nine PG receptors are known to exist, with additional splice variants (see Figure 59-1).[17] The PG receptors belong to three clusters within a distinct subfamily of the GPCR superfamily, with the lone exception of one of the $PGD_2$ receptors ($DP_2$), which belongs to the chemokine receptor subfamily. The *relaxant receptors* for prostacyclin (IP), $PGD_2$ ($DP_1$), and $PGE_2$ ($EP_2$ and $EP_4$) signal through $G_s$-mediated increases in intracellular cyclic adenosine monophosphate (cAMP). The *contractile receptors* for thromboxane $A_2$ (TP), $PGF_{2\alpha}$ (FP), and $PGE_2$ ($EP_1$) signal through a $G_q$-mediated increase in intra-cellular calcium. An *inhibitory receptor* for $PGE_2$ ($EP_3$) couples to $G_i$ and decreases cAMP formation. Note that $PGE_2$ has at least four different receptors with a broad range of potential actions. $EP_4$ in particular appears to mediate many of the pro-inflammatory activities of $PGE_2$.[18] Given the great diversity of PG receptors expressed by different cell types, PG signaling pathways constitute an enormously complex network that controls many biologic actions. Much work must be completed for us to understand fully all of the cellular signaling mechanisms by which PGs and their receptors elicit their respective biologic actions. This is particularly true because antagonists for many of these receptors show promise as novel targets for drug development.[18]

## Biochemistry and Structural Biology

COX-1 and COX-2 are bifunctional enzymes that mediate a COX reaction whereby arachidonate plus two molecules of $O_2$ are converted to the cyclic endoperoxide $PGG_2$, followed by a hydroperoxidase reaction in which $PGG_2$ undergoes a two-electron reduction to $PGH_2$.[8] COX enzymes are integral membrane proteins that sit within the inner leaflet of the lipid bilayer of intra-cellular phospholipid membranes of the nuclear envelope and the endoplasmic reticulum. The crystal structures of COX-1 and COX-2 have been identified, and they have essentially identical domain structures.[6] The COX enzymes are homodimers, with each monomer consisting of three structural domains. The N-terminal, epidermal growth factor–like domain is involved in dimerization via hydrophobic interactions. The membrane-binding domain is composed of four amphipathic α helices lodged into half of the lipid bilayer to form a hydrophobic channel in the center of the large catalytic domain that contains the COX and peroxidase active sites and that constitutes about 80% of the protein. The catalytic domain is globular with two distinct intertwining lobes. The interface of these lobes creates a shallow cleft on the upper surface of the enzyme where the peroxidase active site is located and where heme is bound.

COX and hydroperoxidase reactions occur at distinct but structurally and functionally interconnected sites. The COX reaction is peroxide dependent and requires that the heme group at the peroxidase site undergo a two-electron oxidation. A tyrosine residue (tyrosine 385) located at the COX active site is involved as a reaction intermediate. The physiologic heme oxidant in vivo is not known, but it has been shown that the COX activity of COX-2 can be activated at 10-fold lower concentrations of hydroperoxide than that of COX-1.[8]

NSAIDs function by blocking access of AA to the COX active site within a long, narrow, dead-end, hydrophobic channel whose entrance is framed by the four amphipathic helices of the membrane-binding domain. The channel extends into the globular catalytic domain and is about 8 Å wide. Significant narrowing of the channel occurs where arginine 120 protrudes into the channel. Arginine 120 is essential for binding both AA substrate and most carboxylate-containing NSAIDs in COX-1. By virtue of other differences in the hydrophobic channel, this residue is not essential for binding AA in COX-2, but it remains critical for binding of most carboxylate-containing NSAIDs.[19,20] Serine 530 is required for inhibition of COX by the phenylacetic acid NSAID diclofenac. Serine 530 is also the residue transacetylated by ASA and, along with valine 349, seems to govern the stereochemistry of the pocket such that after exposure to aspirin, AA is sterically blocked from a functional interaction with the catalytic domain in COX-1 and catalytic activity is completely inhibited.

A crucial structural difference between COX-1 and COX-2 is the substitution of the small amino acid valine in COX-2 for the isoleucine with a bulky side chain in COX-1 at position 523 that opens a side pocket in the hydrophobic channel in COX-2.[6] Overall, COX-2 has a wider and somewhat more flexible interior channel, a structural feature that has been exploited with respect to the development of COX-2–selective NSAIDs, as shown in Figure 59-3.[21]

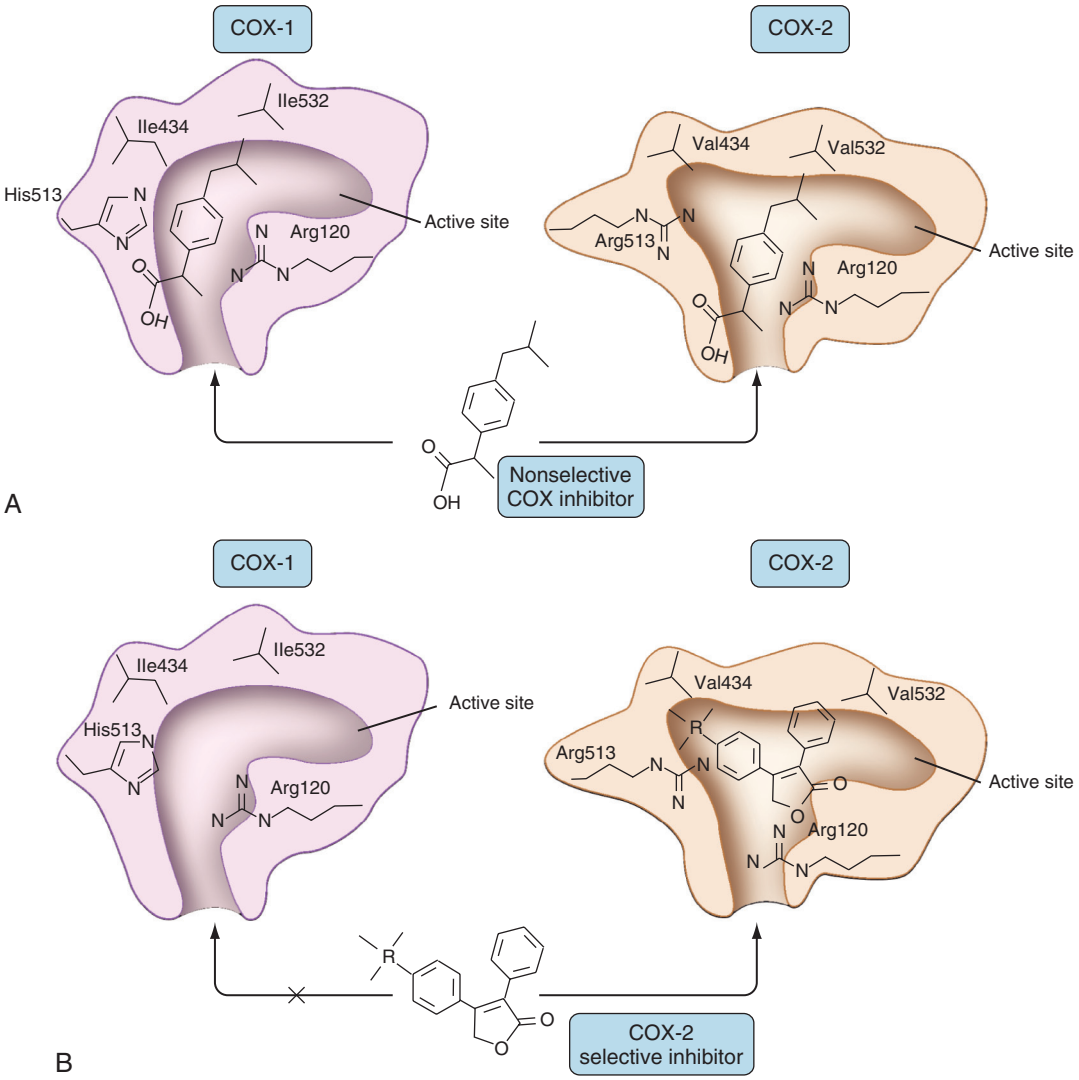

**Figure 59-3** Cyclooxygenase (COX)-1 and COX-2 substrate-binding channels. A schematic depiction of the structural differences between the substrate-binding channels of COX-1 and COX-2 that allowed the design of selective inhibitors. The amino acid residues, Val434, Arg513, and Val523, form a side pocket in COX-2 that is absent in COX-1. **A,** Nonselective inhibitors have access to the binding channels of both isoforms. **B,** The more voluminous residues in COX-1, Ile434, His513, and Ile532, obstruct access of the bulky side chains of the coxibs. *(From Grosser T, Fries S, FitzGerald GA: Biological basis for the cardiovascular consequences of COX-2 inhibition: therapeutic challenges and opportunities.* J Clin Invest *116:4–15, 2006.)*

Both enzymes form homodimers, but the monomers often behave asymmetrically as conformational heterodimers during catalysis and inhibition.[22] That is, when a fatty acid binds to one monomer, the other monomer becomes catalytically active and only one monomer is catalytically active at any one time. The specific fatty acid bound to the noncatalytic monomer can regulate catalytic activity.[23] Different NSAIDs interact differently with respect to allosteric inhibition of COX enzymes as one facet of their pharmacology.[22] ASA acetylation occurs in only one of the two COX monomers, which completely inhibits the activity of COX-1. However, COX-2 retains the ability to form a reduced amount of $PGH_2$ and alternative aspirin-triggered lipoxins from AA. The anti-inflammatory resolvins may be synthesized by ASA-acetylated COX-2 from omega-3 PUFA.[22]

### Molecular Biology

In addition to the differences in their structures relevant for the pharmacology of COX-1 and COX-2 inhibition, physiologically relevant differences exist with respect to expression and regulation.[2,3] Generally, COX-1 is constitutively expressed in most cells, and its expression is minimally altered by inflammatory stimuli. The promoter region of COX-1 has the characteristics of a gene that is continuously transcribed and stably expressed. COX-1 activity is regulated by substrate (AA) availability. When an increase in substrate mobilization occurs via phospholipase $A_2$ activation, a concordant increase occurs in PG synthesis mediated by COX-1. COX-1 is the only isoform expressed in mature platelets and is the most highly expressed COX isoform in normal gastroduodenal mucosa.[24] Because COX-1 is inhibited by nonselective NSAIDs, these physiologic properties may explain some of the common adverse effects of these drugs such as bleeding and GI ulceration.

In contrast, the COX-2 gene has the structure of a highly regulated product with binding sites for transcription factors such as nuclear factor-κB (NF-κB), cAMP-responsive element, and activator protein (AP)-1 which rapidly increase transcription in response to inflammatory signals.[2] COX-2 expression is highly induced by pro-inflammatory cytokines such as TNF and IL-1β, microbial products, and mitogens[2,8] and is inhibited by glucocorticoids.[2] COX-2 messenger RNA (mRNA) stability is a key regulator of COX-2 levels. The potential for instability of the COX-2 message is due to the presence of multiple adenine-uracil$_3$-adenine (AUUUA) instability sequences in the 3′ region that mediate a rapid degradation of mRNA, which ultimately suppresses COX-2 protein synthesis and PG production. Conversely, some stimuli, including IL-1β, may interfere with mRNA degradation and increase COX-2 levels and PG production.[25] COX-1 and COX-2 can be post-translationally modified. COX-1 is glycosylated at three asparagines involved in proper protein folding of the enzyme, whereas COX-2 can be glycosylated at four asparagines.[25,26]

The generalization that COX-1 expression is constitutive and COX-2 expression is inducible has its limitations, given that COX-2 is expressed constitutively in several organ systems and regulated by physiologic, as well as pathologic, stimuli. COX-2 is basally expressed in the brain, kidney, pancreas, and blood vessels and therefore plays an important role in normal reproductive, renal, cardiovascular, and skeletal physiology.[2,21,27]

## MECHANISM OF ACTION

### Cyclooxygenase Inhibition

All of the NSAIDs are synthetic inhibitors of the COX active site, but subtle mechanistic differences in the manner in which individual NSAIDs interact and bind with the active site are responsible for some of the differences in their pharmacologic characteristics.[28] ASA is the only covalent, irreversible modifier of COX-1 and COX-2, whereas all of the other NSAIDs are competitive inhibitors, competing with AA for binding in the active site. The competitive inhibitors are subdivided further on the basis of whether they bind to the COX active site in a time-dependent or time-independent manner.

Crystallographic studies have shown how ASA acetylates serine 530 of COX-1. Similar to other NSAIDs, ASA diffuses into the COX-1 active site at the mouth of the channel and travels to the constriction created by arginine 120, where it is in the best orientation to transacetylate serine 530, leading to the complete and irreversible inhibition of COX-1.[29] In COX-2, the channel of the active site is larger than COX-1, the orientation of ASA for serine 530 attack is not as good, and transacetylation efficiency for COX-2 is 10-fold to 100-fold less than for COX-1. ASA can also "trigger" COX-2 to alter its catalytic activity to produce 15 R-HETE and lipoxins from AA and to generate anti-inflammatory lipids from omega-3–PUFA.[11]

The time it takes for an NSAID to inhibit the COX active site relative to how long it takes for it to leave the COX channel is a crucial factor in the inhibition of COX.[30] Drugs such as ibuprofen exhibit such rapid rates that they essentially inhibit COX instantly but can be removed from the COX active site just as quickly when drug levels decrease. Both COX monomers must be inhibited by ibuprofen to block catalytic activity.[22] Conversely, indomethacin and diclofenac are time-dependent allosteric inhibitors that require seconds to minutes to bind to the COX active site and need only block one of the COX monomers to completely inhibit catalytic activity.[22] These NSAIDs also need hours to exit the COX active site. Initially, most traditional time-dependent NSAIDs form a loose complex with the COX active site before a stronger interaction is established. This complex is limited by the time it takes the drug to become properly oriented within the COX channel at arginine 120, the constriction site in the COX channel. This orientation may involve a change in conformation to the "open state" to allow the drug to access the upper part of the COX catalytic site.

Drugs such as flurbiprofen and indomethacin form a salt bridge between the carboxylate moiety of the NSAID and the guanidinium moiety of arginine 120. Hydrophobic interactions between the aromatic rings and the hydrophobic amino acids in the channel aid binding. Such interactions at the constriction point of the channel completely block the entry of substrate to the active site.[31] Diclofenac interacts with serine 530, not arginine 120, but also blocks entry of substrate.[32]

## COX-2 Selectivity

NSAIDs such as meloxicam, nimesulide, and etodolac show some selectivity for inhibiting COX-2 compared with COX-1. After the discovery of COX-2, efforts to further enhance COX-2 selectivity led to the development of celecoxib, rofecoxib, valdecoxib, etoricoxib, and lumiracoxib. The prototypical COX-2-selective NSAIDs, celecoxib and rofecoxib, are diaryl compounds containing a sulfonamide (celecoxib) and methylsulfone (rofecoxib) rather than a carboxyl group. Both drugs are weak time-independent inhibitors of COX-1 but strong time-dependent inhibitors of COX-2 that require their entry into and stabilized binding in the catalytic pocket. Because these drugs lack a carboxyl group, arginine 120 is not involved, but multiple sites of hydrogen and hydrophobic binding stabilize drugs at the catalytic site. The sulfur-containing phenyl ring of COX-2–selective NSAIDs plays a pivotal role in binding stability by occupying the hydrophobic side pocket characteristic of the COX-2 catalytic site. If this side pocket is removed by mutagenesis, all isozyme selectivity is lost.[6]

Most commonly, COX isozyme selectivity is defined by using the concentration of drug required to inhibit PG production by 50% in a particular assay system (inhibitory concentration [IC]50). Ratios using values obtained for COX-1 IC50s compared with COX-2 IC50s can be calculated and used as a standard measure for comparing the degrees of selectivity of a particular NSAID for one or the other COX isoform.[33] PG assay systems can vary widely, however, making it difficult to directly compare results from studies using different assay systems. To circumvent such problems, most clinicians have accepted the use of the in vitro whole-blood assay to compare NSAID selectivities. In this system, COX-1 inhibition is assessed as a function of the reduction of thromboxane made by platelets after clot formation. Inhibition of COX-2 is based on the inhibition of $PGE_2$ production in a heparinized blood sample after LPS stimulation. A COX-2–selective NSAID lacks inhibitory effect on platelet COX-1 at concentrations at or above those that maximally inhibit COX-2.[5,34]

## Cyclooxygenase-Independent Mechanisms of Action

At high, nonphysiologic concentrations, some NSAIDs seem to elicit effects on cellular pathways in vitro that do not involve the inhibition of COX. Because of the high doses of drug required and the use of in vitro systems, the relevance of these effects to in vivo activity is uncertain. Some NSAIDs inhibit phosphodiesterases associated with the metabolism of cAMP, leading to increased intra-cellular cAMP levels and the subsequent general inhibition of peripheral blood lymphocyte responses to mitogen stimulation, monocyte and neutrophil migration, and neutrophil aggregation.[35] NSAIDs scavenge free radicals, inhibit superoxide production by polymorphonuclear neutrophils, reduce mononuclear cell phospholipase C activity, and inhibit inducible nitric oxide (NO) synthase activity. Sodium salicylate and ASA inhibit NF-κB activation, as do certain inactive enantiomers of flurbiprofen. Some reports indicate that other cell signaling molecules such as mitogen-activated protein kinases and the transcription factor AP-1 also may be modulated by NSAIDs. Some NSAIDs bind to and activate members of the peroxisome proliferator-activated receptor (PPAR) family and other intra-cellular receptors. PPAR activation is thought to mediate anti-inflammatory activities. Nonselective acidic NSAIDs, including salicylate, ibuprofen, and diclofenac, but not nonacidic drugs, activate AMP-activated kinase.[36] Selective COX-2 inhibitors may have unique structural features that promote COX-independent activities such as cell-cycle regulation, apoptosis, and antiangiogenesis.[37]

## Mechanism of Acetaminophen and Other Analgesic Antipyretic Drugs

Acetaminophen (paracetamol) and dipyrone relieve pain and fever, but they are not anti-inflammatory. The precise mechanisms by which these drugs elicit their effects remain unclear. In the 1970s, it was proposed that acetaminophen worked by means of a "central" action by inhibiting COX activity primarily in the brain and not in peripheral tissues because they were not acidic and could cross the blood-brain barrier.[38] Acetaminophen does inhibit COX-1 and COX-2, but variably, in a manner dependent on cell and tissue type. Acetaminophen does not appear to inhibit by interacting with the COX active site; rather, it serves as a reducing co-substrate for the peroxidase site. The peroxide tone of cells and tissues in vivo may be responsible for inhibitor specificity, with platelets and activated macrophages being resistant to the action of acetaminophen and vascular endothelial cells being sensitive to its inhibitory effects on COX. Additionally, the inhibitory potency of acetaminophen is determined by the concentration of the COX enzyme.[38] This phenomenon may be an additional factor for the lack of clinical anti-inflammatory effects, because inflammation is associated with a markedly increased expression of the COX-2 enzyme. With the discovery of a COX-1 splice variant and studies showing that it is both highly expressed in brain and more sensitive to inhibition by acetaminophen, some investigators proposed that the analgesic and antipyretic actions of acetaminophen could be explained by its ability to inhibit the COX-1 splice variants (called COX-3 by some investigators, despite the fact that this variant does not arise from a unique gene).[39] However, more recent studies have rejected this mechanism as explanatory for the effects of acetaminophen.[38,40]

Salicylate has analgesic, antipyretic, and anti-inflammatory activity, but similar to acetaminophen and in contrast to ASA, it is a poor COX inhibitor. Salicylate also inhibits COX activity if substrate levels are low, and it is also dependent on the oxidative state of the enzyme, suggesting that this drug may inhibit COX by redox-related mechanisms.[41]

# PHARMACOLOGY AND DOSING

## Classification

NSAIDs are generally grouped according to their chemical structures, plasma half-life, and COX-1 versus COX-2 selectivity (Table 59-1 and Figure 59-4). Table 59-1 presents a representative compilation of common NSAIDs, formulations, dosages, half-lives, and precautions. Structurally, most

**TABLE 59-1** Common NSAIDs

| Drug | Brand Names | Available Formulations (mg) | Maximal Daily Dose (mg) | Tmax (hr) | Half-life (hr) | Dose Adjustment or Special Precautions |
|---|---|---|---|---|---|---|
| **Salicylic Acids** | | | | | | |
| Acetylsalicylic acid | Aspirin | Tablets: 81, 165, 325, 500, 650<br>Children's: 81<br>Suppository: 120, 200, 300, 600 | 3000 | 0.5 | 4-6 | Decrease dose by 50% in patients with renal failure and hepatic insufficiency |
| Salsalate | Disalcid<br>Amigesic<br>Salflex | Capsule: 500<br>Tablet: 500, 750 | 3000 | 1.4 | 1 | |
| Diflunisal | Dolobid | Tablets: 250, 500 | 1500 | 2-3 | 7-15 | Decrease dose by 50% in patients with renal failure |
| **Acetic Acids** | | | | | | |
| Diclofenac | Voltaren<br>Voltaren XR<br>Cataflam | Tablets: 25, 50, 75<br>Extended release: 100 | 225 | 1-2 | 2 | Incidence of increased transaminase levels higher than with other NSAIDs |
| Diclofenac + misoprostol | Arthrotec | Tablets: 50 or 75 plus misoprostol 200 µg | 200 | 1-2 | 2 | Incidence of increased transaminase levels higher than with other NSAIDs |
| Indomethacin | Indocin<br><br>Indocin SR | Caps: 25, 50<br><br>Sustained release: 75<br>Oral suspension: 25 mg/5 mL<br>Suppositories: 50 | 200 | 1-4 | 2-13 | Approved for treatment of patent ductus arteriosus |
| Sulindac | Clinoril | Tablets: 150, 200 | 400 | 2-4 | 16 | Prodrug metabolized to active compound<br>Decrease dose in patients with renal and liver disease and in elderly patients |
| Ketorolac | Toradol | IM/IV: 15 or 30 mg/mL<br><br>Tablets: 10 | 120 IV/IM<br><br>40 mg PO | 0.3-1 | 4-6 | Decrease dose by 50% in patients with renal failure and in elderly patients<br>Do not use >5 days |

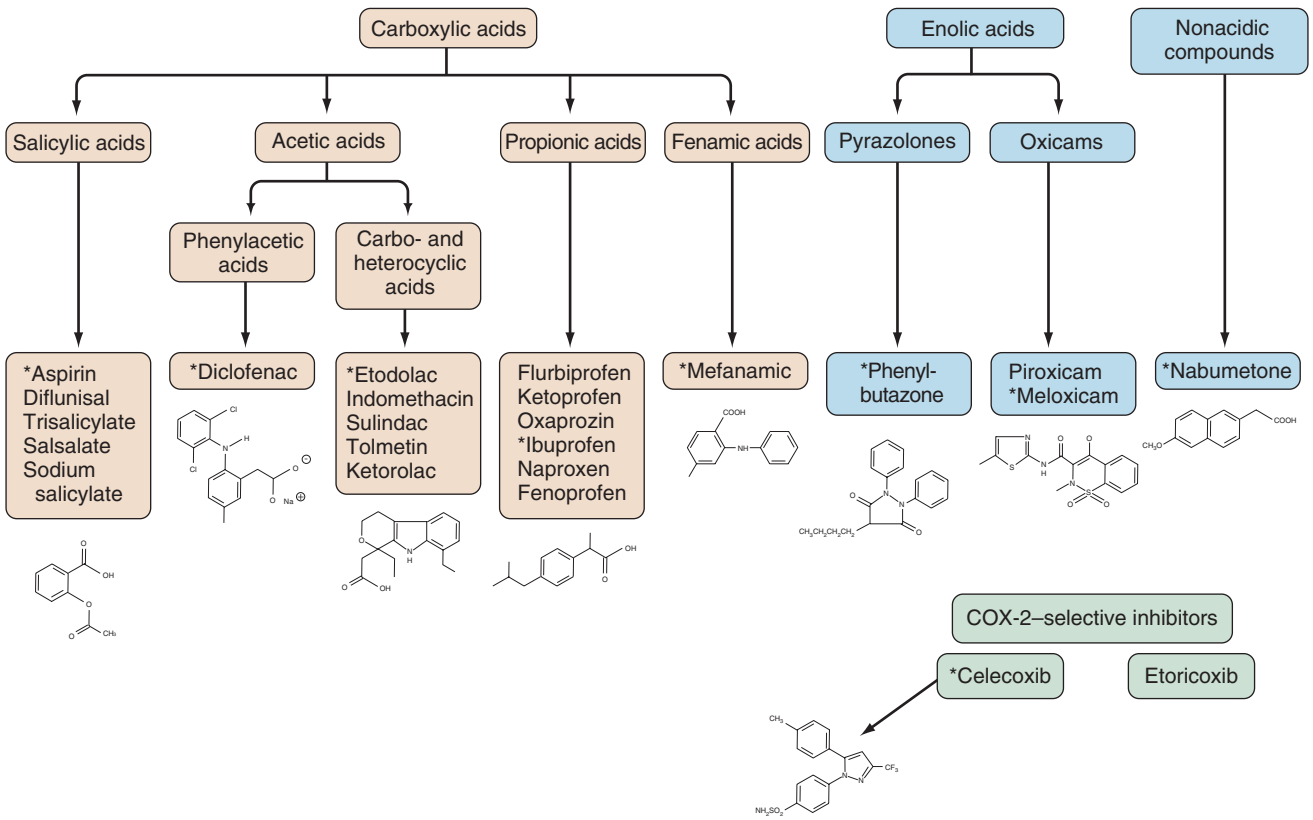

**Figure 59-4** Classification and representative structures of the traditional NSAIDs and cyclooxygenase-2 (COX-2)–selective NSAIDs. *Selected NSAID structure from each subclass.

NSAIDs are organic acids with low pK values that lend themselves to their accumulation at sites of inflammation—areas that often exhibit lower pH values than do uninvolved sites. The persistence of NSAIDs in the synovial fluid is associated with a sustained therapeutic effect despite relatively rapid clearance from the plasma, vascular wall, and kidneys.[42] Usually a direct relationship exists between low pK and a short half-life, but there are exceptions, such as nabumetone, which is nonacidic. Classifying NSAIDs on the basis of plasma half-life can be problematic, given the fact that these drugs tend to accumulate in synovial fluid, where the concentration of the drug may remain more stable than in the plasma. Short–half-life NSAIDs potentially could be given less frequently than indicated by their plasma half-life. NSAIDs exhibiting longer half-lives require more time to reach steady-state plasma levels. Drugs with a half-life greater than 12 hours can be given once or twice a day. Plasma levels increase for a few days to several weeks (depending on the specific half-life) but then tend to remain constant between doses. NSAIDs with longer half-lives also enable drug concentrations to equilibrate between the plasma and the synovial fluid, although total bound and unbound drug levels are usually lower in synovial fluid because less albumin is present in synovial fluid than in plasma. However, NSAIDs with longer half-lives or extended-release formulation may be associated with an increased propensity to cause adverse effects.[43] COX-isozyme selectivity is likely to be a critically important factor in determining relative GI and cardiovascular risk, which also should be considered in addition to other pharmacologic properties for each NSAID.[33]

## NSAID Metabolism

Almost all NSAIDs are more than 90% bound to plasma proteins. If total drug concentrations are increased beyond the point at which the binding sites on albumin are saturated, biologically active free drug concentrations increase disproportionately to the increasing total drug concentration. The clearance of NSAIDs is usually by hepatic metabolism, with production of inactive metabolites that are excreted in the bile and urine. Most NSAIDs are metabolized through the microsomal cytochrome P450-containing mixed-function oxidase system. NSAIDs are most often metabolized by CYP3A, CYP2C9, or both. However, some NSAIDs are metabolized by other cytosolic hepatic enzymes.

## Salicylate Metabolism and Aspirin Resistance

Salicylates are acetylated (e.g., aspirin) or nonacetylated (e.g., sodium salicylate, choline salicylate, choline magnesium trisalicylate, and salicylsalicylic acid).[41] Although the nonacetylated salicylates are only weak inhibitors of COX in vitro, they are able to reduce inflammation in vivo. Aspirin is rapidly deacetylated to salicylate, both spontaneously and enzymatically. Differences in the formulation of these agents affect the absorption properties, but not bioavailability. Buffered aspirin tablets contain antacids that increase the pH of the microenvironment, whereas enteric coating slows absorption. The bioavailability of rectal aspirin suppositories increases with retention time. Salicylates primarily bind to albumin and rapidly diffuse into most body fluids. Salicylate is metabolized principally by the liver and excreted primarily by the kidney. In the kidney, salicylate and its metabolites are freely filtered by the glomerulus, then reabsorbed and secreted by the tubules. Salicylate serum levels usually do not correlate well with dosage, however, and small increases in dosage may result in disproportionate increases in serum levels. The drug clearance rate is a function of serum concentration. The primary factors regulating serum salicylate levels are urinary pH and metabolic enzyme activity.

The term "aspirin resistance" is broadly used to describe the failure of aspirin to prevent a thrombotic event, whether as a result of pharmacologic resistance to the anti-platelet effects of aspirin or the inability of aspirin to overcome thrombophilia in a given clinical setting.[44] Factors such as sex, genetic polymorphisms, and clinical factors, including smoking, obesity, and diabetes, may alter aspirin effects on platelet function. Lack of adherence and drug interactions also may play a role in aspirin resistance.

## Pharmacologic Variability

Different patients can respond to the same NSAID in a variety of ways, and the basis for this individual variability remains unclear. Several pharmacologic factors related to NSAIDs may influence this variability, such as dose response, plasma half-life, enantiomeric conversion, urinary excretion, and pharmacodynamic variation.[45] Other important drug factors include protein binding, the metabolic profile of the drug, and the percentage of the drug that is available as the active *(S)* enantiomer. Some NSAIDs exist as two enantiomers; these NSAIDs include the propionic acid derivatives ibuprofen, ketoprofen, and flurbiprofen, which exist as mixtures of inactive *(R)* and active *(S)* enantiomers. Naproxen is composed of the active *(S)* enantiomer. Conversion of the propionic acid NSAIDs from the inactive *(R)* enantiomer to the active *(S)* enantiomer occurs in vivo to various degrees, providing some basis for the variability in patient response. Genetic variability also exists in the cytochrome P450 metabolic enzymes, and consequently some people or ethnic groups metabolize drugs more slowly. For example, Asians frequently experience slow metabolism through the CYP2C9 pathway. A number of single-nucleotide polymorphisms in the genetic sequence of *CYP2C9* have been described, and the product of one of these altered genes, CYP2C9*2, is associated with reduced metabolism of celecoxib and an accompanying increase in plasma concentration of the drug.[42] Finally, the pharmacokinetics of some NSAIDs are affected by hepatic disease, renal disease, or old age.

## Routes of Drug Delivery

NSAIDs are produced in a variety of dosage forms, including intravenous, slow-release, and sustained-release oral preparations, topical preparations in various forms, including gels and patches, and suppositories. Given the desire to reduce NSAID toxicity while preserving drug delivery to a specific site, efforts continue to alter drug formulation and delivery systems. Nanoparticles, liposomes, and microspheres are under investigation to allow dose reduction and

specific targeting. Intra-articular delivery is under consideration, but because joints have efficient lymphatic clearance systems, the utility of this form of targeting remains to be proved.

Topical NSAID formulations were developed to reduce systemic exposure while preserving efficacy. Diclofenac, for example, is available as a solution, gel, or patch. The systemic effects are directly proportional to the surface area, and this method of delivery results in a relatively stable systemic level of diclofenac compared with oral administration.[46]

### Combination Drugs

NSAIDs have also been combined with agents that have gastroprotective effects in the form of "polypills" that are currently available on the market. This strategy may increase compliance with effective protective agents, thereby reducing adverse effects in clinical practice. Combining diclofenac with the synthetic $PGE_1$ analogue misoprostol reduces the risk of NSAID-related peptic ulcerations and mucosal injury, but utility of the combination is often limited by misoprostol-induced cramping and diarrhea.[47] In population-based studies, the combination pill was more effective than diclofenac and misoprostol co-prescription in preventing hospitalization for peptic ulcer disease or GI hemorrhage.[48] The combination of enteric-coated naproxen and the proton pump inhibitor (PPI) esomeprazole into a single pill has been approved by the FDA. This agent reduces endoscopically detected gastric ulcers.[49]

A different strategy is NO-releasing NSAIDs (NO-NSAIDs), which are synthesized by the ester linkage of an NO-releasing moiety to conventional NSAIDs, including aspirin, flurbiprofen, diclofenac, sulindac, and others.[50] The NO moiety is slowly released by enzymatic activity in vivo, likely by esterases, resulting in slow accumulation of the parent NSAID. The lower rate of GI ulceration associated with these drugs is likely related to NO-associated vasodilation and the relatively lower concentration of the parent NSAID.

## THERAPEUTIC EFFECTS

### Anti-inflammatory Effects

NSAIDs are frequently used as first-line agents for the symptomatic relief of many different inflammatory conditions. In double-blind, randomized clinical trials of inflammatory arthritis, NSAIDs have been compared with placebo, aspirin, and each other. Clinical trials of NSAID efficacy in RA (and osteoarthritis) usually employ a design whereby the current NSAID is discontinued and the patient must have an increase in symptoms or flare to enter the study. Although primary outcome measures have some variation, most include parameters that make up the American College of Rheumatology (ACR)20. Efficacy superior to that of placebo is easily demonstrated for NSAIDs within 1 to 2 weeks in patients with active RA who are not receiving corticosteroids or other anti-inflammatory medications.[51] Comparisons of adequate doses of traditional NSAIDs or COX-2–selective NSAIDs with one another almost always show comparable efficacy. Despite improvement in pain and stiffness with NSAIDs, these agents do not usually reduce acute phase reactants, nor do they modify radiographic progression. The anti-inflammatory effects of NSAIDs have also been demonstrated in rheumatic fever, juvenile RA, ankylosing spondylitis, gout, osteoarthritis, and systemic lupus erythematosus (SLE). Although not as rigorously proven, their efficacy is also accepted in treatment of reactive arthritis, psoriatic arthritis, acute and chronic bursitis, and tendinitis.

### Analgesic Effects

Virtually all NSAIDs relieve pain when used in doses substantially lower than those required to suppress inflammation. The analgesic action of NSAIDs is due to inhibition of PG production in peripheral tissues and in the central nervous system (CNS). In the periphery, PGs do not induce pain per se but rather sensitize peripheral nociceptors to the effects of mediators such as bradykinin or histamine.[52] PGs released during inflammation or other trauma lower the activation threshold of tetrodotoxin-resistant sodium channels on sensory neurons. In the CNS, where NSAIDs and acetaminophen exert analgesic effects, PGs also play an important role in neuronal sensitization. COX-2 is constitutively expressed in the dorsal horn of the spinal cord, and its expression is increased during inflammation.[53] Centrally generated $PGE_2$ activates spinal neurons and also microglia that contribute to neuropathic pain.[54] Both COX-1 and COX-2 play a role in nociception as demonstrated by reductions in experimental pain in mice deficient in either COX-1 or COX-2.[55]

### Antipyretic Effects

The NSAIDs and acetaminophen effectively suppress fever in humans and in animals included in experiments. Fever results from the production of PG, primarily $PGE_2$, from vascular endothelial cells via COX-2 and mPGES-1.[56] These PGs generate neuronal signals that activate the thermoregulatory center in the preoptic area of the anterior hypothalamus. $PGE_2$ synthesis is stimulated by endogenous (e.g., IL-1) or exogenous (e.g., LPS) pyrogens. Mice with a targeted deletion of either the COX-2 or mPGES-1 genes fail to develop fever in response to inflammatory stimuli.[57]

Little evidence suggests that any NSAID has superior efficacy as an antipyretic agent. However, in fever associated with viral illnesses, aspirin should be avoided because of the association with hepatocellular failure (Reye's syndrome).[58]

### Other Therapeutic Effects

#### Anti-platelet Effects

Aspirin and traditional NSAIDs inhibit platelet COX-1 to variable degrees. Except for aspirin, inhibition of platelet aggregation is reversible and depends on the concentration of drug in the platelet. Aspirin acetylates platelet COX-1, which cannot be resynthesized. The antiaggregation effect of as little as 80 mg of aspirin can last for up to 4 to 6 days, until the bone marrow can synthesize new platelets.[59]

On the basis of accumulated data showing its benefits, the FDA has approved ASA for use in the secondary prevention of cardiovascular disease. Major trials have shown that meaningful decreases in nonfatal myocardial infarction (MI), nonfatal stroke, and death can be realized by daily administration of ASA of 75 to 325 mg. Major vascular events can be reduced by 10 to 20 events for every 1000 patients treated, at a cost of one to two major GI bleeds.[60]

In the Nurses Health Study of primary prevention of major vascular events, no reduction in rates of MI was observed with the use of ASA, 100 mg every other day, whereas rates of GI bleeding were increased. However, stroke rates were significantly reduced with use of this regimen.[61] The U.S. Preventative Health Task Force has updated its recommendations to encourage use of low-dose ASA in men aged 45 to 79 years and in women aged 55 to 79 years.[60] ASA used for primary prevention of cardiovascular events appears to lower the risk for MI in men and for stroke in women.[62]

### Cancer Chemoprevention

A large body of epidemiologic and animal studies provides evidence that a high-fat diet can be associated with a risk for cancer. AA, one of the major ingredients of animal fats, and the eicosanoids derived from AA are important contributors to the development of cancer.[10] Large-scale epidemiologic studies have long indicated that long-term NSAID use reduces the incidence of a variety of cancers, including colon, intestinal, gastric, breast, and bladder, by 40% to 50%.[10] Given the ability of NSAIDs to inhibit COX and PG production, the COX pathway immediately becomes implicated as playing an important role in the pathogenic process. It is well recognized that growth factors, tumor promoters, and oncogenes stimulate PG production via the induction of COX-2 and that human tumorigenic tissues exhibit increased COX activity compared with their normal, nontumorigenic counterparts. COX-2 is overexpressed in 80% of colorectal cancer tissues. Among the PGs, $PGE_2$ is most abundant in human neoplasms. The inducible mPGES-1 enzyme is highly expressed in tumors, and its absence suppresses intestinal tumorigenesis in animal models. Furthermore, the enzyme that metabolizes intracellular $PGE_2$, 15-hydroxyprostaglandin dehydrogenase, is ubiquitously lacking in tumors, and mice with a genetic deletion of this enzyme have accelerated tumorigenesis.[10] Many natural products, including resveratrol (red wine), catechins (green tea), and curcumin (saffron), also inhibit COX, which may be an important mechanism underlying their putative cancer-preventing effects.[63]

A retrospective cohort study shows that aspirin and traditional NSAIDs specifically reduce cancer risk in the subgroup of patients whose colon tumors express higher levels of COX-2.[64] In a meta-analysis of the effects of ASA (75 mg daily and upward without dose dependence) on cancer, allocation to receive aspirin reduced death due to cancer by more than 20%.[65] Upon analysis of individual patient data, a cancer death benefit was apparent only after 5 years of follow-up, and the benefit increased with scheduled duration of trial treatment. ASA effects appear to be greater on adenomatous cancer than on other cancer types. Other studies demonstrated a reduction in both the incidence of colorectal cancer and death from colorectal cancer, particularly for cancers of the proximal colon.[66] Long-term low-dose ASA use also appears to reduce the risk of prostate cancer.[67]

Clinical trials also demonstrated that traditional and COX-2–selective NSAIDs could cause regression of polyps in patients with familial adenomatous polyposis (FAP).[68] Celecoxib was subsequently approved by the FDA for reduction of polyps in patients with FAP. Although NSAIDs are still among the most promising chemopreventative agents for cancer, cardiovascular and GI adverse effects have dampened enthusiasm.[10] Alternative strategies for blocking effects of $PGE_2$ and other eicosanoids need to be evaluated to determine their effectiveness as cancer prevention and adjunct therapy.

## ADVERSE EFFECTS

NSAIDs share a common spectrum of clinical toxicities, although the frequency of particular adverse effects varies with the compound (Table 59-2). The hazard of individual NSAIDs is related to their pharmacologic characteristics, such as bioavailability and half-life, as well as their potency for inhibition of COX-1 and COX-2.[33,43,69]

### Gastrointestinal Tract Effects

NSAIDs cause GI injury through both topical and systemic effects. After a mucosal injury occurs, NSAIDs inhibit the

**TABLE 59-2** Shared Toxicities of NSAIDs

| Organ System | Toxicity |
|---|---|
| Gastrointestinal | Dyspepsia<br>Esophagitis<br>Gastroduodenal ulcers<br>Ulcer complications (bleeding, perforation, obstruction)<br>Small bowel erosions and strictures<br>Colitis |
| Renal | Sodium retention<br>Weight gain and edema<br>Hypertension<br>Type IV renal tubular acidosis and hyperkalemia<br>Acute renal failure<br>Papillary necrosis<br>Acute interstitial nephritis<br>Accelerated chronic kidney disease |

| Bone | Delayed healing |

*Reduced risk in cyclooxygenase-2–selective NSAIDs.

early events necessary to repair superficial injury, as well as later events of cell proliferation and angiogenesis, leading to delayed ulcer healing.[70] Topical injury initiates the initial mucosal erosions by disrupting the gastric epithelial cell barrier, but PG depletion is essential for the development of clinically significant gastric and duodenal ulcers. The propensity of specific NSAIDs to cause acute topical injury depends on the pKa, with most NSAIDs being weak organic acids. Aspirin is particularly prone to cause mucosal injury when administered orally.[24] Nonacidic NSAIDs such as nabumetone, etodolac, and celecoxib do not cause acute mucosal lesions. Esterification of acidic NSAIDs, such as the case for NO-NSAIDs, suppresses mucosal injury.[24]

Acidic NSAIDs accumulate in gastric epithelial cells and lead to generation of reactive oxygen species. NSAIDs also may cause apoptosis, which appears independent of COX inhibition. They also associate with extra-cellular phospholipids, resulting in attenuation of the hydrophobic surface barrier of the stomach.[71] Phospholipids associated with cell membranes are disrupted, leading to increased permeability and acid or bile back diffusion.

The integrity of mucosal defense depends on generation of $PGE_2$ and $PGI_2$ from COX enzymes. COX-1 is abundantly expressed under basal conditions in gastric mucosa, whereas COX-2 is almost undetectable. However, both COX-1 and COX-2 are rapidly upregulated after injury or when pre-existing ulcers are present,[72] which may explain the observation that concurrent *Helicobacter pylori* infection increases the risk of developing peptic ulcers and increases bleeding in people who use NSAIDs.[73]

It appears that concurrent COX-1 and COX-2 inhibition is associated with the highest propensity to develop gastric ulcers.[43] This clinical observation is consistent with animal studies whereby mice deficient for a single COX enzyme or treated with drugs that specifically inhibit either COX-1 or COX-2 do not develop ulceration. Severe gastric lesions are seen when both enzymes are simultaneously blocked. However, when the gastric mucosa is damaged, inhibition of either COX-1 or COX-2 is associated with the development of ulcers.[70] Traditional and COX-2–selective NSAIDs delay ulcer healing, with nonselective NSAIDs doing so to a greater degree.[74] It also should be noted that GI bleeding may be related to the combination of injury and inhibition of platelet aggregation, which is an additional factor in the propensity of aspirin and other nonselective NSAIDs to cause clinically apparent ulcers.[24,70]

## Dyspepsia

Nonulcer dyspepsia is the most common adverse event (10% to 20%) associated with use of NSAIDs and may account for poor tolerability.[75] Dyspepsia is more often reported in younger than in older patients.[76] Although they are expected to reduce dyspepsia, COX-2–selective NSAIDs are also associated with a substantial level of adverse GI symptoms.[75] PPIs reduce dyspepsia in controlled trials.[74] Studies have shown that histamine-2 receptor antagonists (H2RAs) are also effective for reducing dyspepsia.[77] Crucially from a clinical perspective, subjective symptoms of dyspepsia, fecal blood loss, and endoscopic findings correlate poorly. Furthermore, only a minority of patients with serious GI events report antecedent dyspepsia.[78]

## Gastritis and Gastroduodenal Ulcer

Up to 25% of long-term NSAID users will experience ulcer disease, and 2% to 4% of the ulcers will bleed or perforate. These GI events result in more than 100,000 hospital admissions annually in the United States and between 7000 and 10,000 deaths, especially in patients with the highest risk.[47] The risk for ulcer complications appears highest within the first 3 months of use but remains present with longer-term therapy. A recent meta-analysis of observational studies on NSAIDs and upper GI bleeding or perforation published between 2000 and 2008 demonstrated a relative risk of 4.50 (95% confidence interval [95% CI], 3.82 to 5.31) for traditional NSAIDs and 1.88 (95% CI, 0.96 to 3.71) for selective COX-2 inhibitors.[43] For traditional NSAIDs, low and medium doses were associated with a lower risk than were higher doses. Several NSAIDs had a far higher than average risk, including ketorolac, with a risk of 14.54 (95% CI, 5.87 to 36.04), and piroxicam, with a risk of 9.94 (95% CI, 5.99 to 16.50). The risks for celecoxib (1.42; 95% CI, 0.85 to 2.37) and ibuprofen (2.69; 95% CI, 2.17 to 3.33) were lower than for NSAIDs overall. Relative risk for other commonly used NSAIDs, including naproxen, indomethacin, meloxicam, and diclofenac, ranged from 3.98 to 5.63. Drugs with a long half-life or slow-release formulation were associated with higher risk, even accounting for dose.[43] Profound and coincident inhibition of both COX-1 and COX-2 using whole blood assay, as seen for ketorolac, piroxicam, naproxen, ketoprofen, and indomethacin, was associated with a relative risk of greater than 5 for GI bleeding and perforation.[43] The use of low-dose aspirin, even in the absence of other risk factors, increases risk for bleeding and death. Many patients taking low-dose aspirin may do so without the knowledge of their physician, and thus it is essential to query patients specifically on this point.

Other patient-specific factors influence the overall risk for GI ulcers and ulcer complications (Figure 59-5).[47,79] A previous history of ulcer or ulcer complications is an important risk, especially if combined with other risks. Infection with *H. pylori* is likely to be associated with additive effect.[73] It remains unclear if eradication of *H. pylori* would be useful in the primary prevention of NSAID-induced ulcers, but it may be advantageous in patients requiring long-term use of NSAIDs.[47] Eradication alone is insufficient as a single strategy for secondary prevention of ulcer complications. This strategy appears to be most effective in reducing the bleeding risk of patients taking low-dose aspirin but is less useful than use of PPIs in patients taking NSAIDs.[47]

Table 59-3 provides recommendations for patients who need NSAIDs and have GI risks.[47] Misoprostol is as effective in the reduction of gastroduodenal ulcers. Meta-analysis showed a reduction of 74% in gastric ulcers and 53% in duodenal ulcers when compared with placebo.[80] The effectiveness of misoprostol is comparable with the PPI lansoprazole.[81] However, the high prevalence of abdominal cramping and diarrhea limit misoprostol use at full doses. For people who do not tolerate full doses (200 μg four times

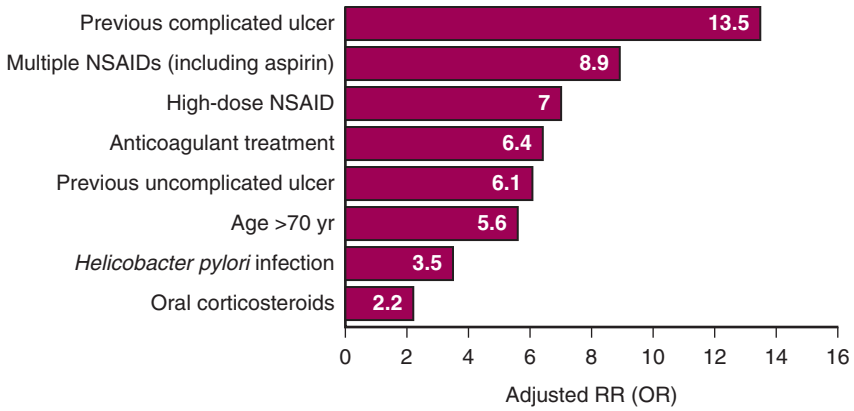

**Figure 59-5** Established risk factors for upper gastrointestinal bleeding associated with NSAID use. daily), lower doses of 400 to 600 μg/day may be useful and comparable with PPIs.

PPIs have been used extensively for prevention of NSAID-induced ulcers and are also used for ulcer healing. Their excellent tolerability and availability over the counter have led to their dominance as pharmacologic agents for preventing NSAID-induced gastroduodenal ulcers. Studies have shown a reduction in the endoscopic ulcer rate from 17% in patients taking traditional or COX-2–selective NSAIDs plus placebo to 5.2% and 4.6% in patients taking NSAIDs plus esomeprazole 20 mg or 40 mg, respectively.[82] As noted previously, a combination pill containing naproxen and esomeprazole has been approved for use. It may reduce noncompliance but will be associated with higher cost.

High-dose, twice-daily doses of H2RA reduce the risk of NSAID-induced endoscopic ulcers and are the least costly alternative. However, these agents are inferior to PPIs and, as with PPIs, no randomized clinical outcome trials have been performed to evaluate the efficacy of H2RAs in long-term users of NSAIDs.[24]

### Esophageal Injury

Aspirin and NSAIDs are associated with esophagitis as a result of mechanisms similar to those in the gastric mucosa.[83,84] Esophageal emptying may be slowed in elderly persons, resulting in a prolonged exposure of the mucosa to the irritant action of aspirin and NSAIDs. Gastroesophageal reflux may be an aggravating factor and may lead to stricture formation. Bleeding also may complicate esophagitis. NSAIDs should be prescribed with caution in the presence of gastroesophageal reflux disease.

### Small Bowel Injury

The availability of video capsule endoscopy (VCE) and balloon enteroscopy has advanced the ability to detect small intestinal lesions in patients taking NSAIDs. NSAIDs can cause a concentric "diaphragm-like" stricture in the small bowel, in addition to causing mucosal injury and bleeding. Two recent studies of patients taking NSAIDs for at least 3 months using VCE demonstrated a prevalence for small bowel injuries of 70% to 80%.[85] Furthermore, NSAID-induced small bowel injury is likely a common cause of obscure GI bleeding. NSAIDs that undergo enterohepatic circulation are likely to be associated with higher risk. Small bowel injury may be detected by anemia or symptoms of obstruction related to a stricture.[85] Strategies effective for gastroduodenal ulcers such as misoprostol or certain PPIs also may reduce the risk for small bowel mucosal injury. Strictures may require balloon endoscopy or surgical intervention.[85]

### Colitis

NSAIDs cause erosions, ulcers, hemorrhage, perforations, strictures, and complications of diverticulosis in the large bowel.[86] NSAID-induced injury is more common in the right colon (80%) but can occur in the transverse and left

colon. Suppositories containing NSAIDs can cause erosions, ulcers, and stenoses in the rectum. NSAID colonopathy is in the differential diagnosis of inflammatory bowel disease. Patients with NSAID-induced colonopathy are typically older, and the erosions are more likely to be transverse or circular.[87] There is also a concern that treatment with traditional and COX-2–selective NSAIDs may exacerbate inflammatory bowel disease.[88] NSAIDs are also implicated in the development of collagenous colitis.[89]

## Renal Effects

PGs play a vital role in solute and renovascular homeostasis.[90] It is becoming quite clear that PGs are produced by both COX-1 and COX-2, generally in different locations within the kidney, and that these PGs may play different physiologic roles in renal function.[91,92] COX-1 is highly expressed in the renal vasculature, glomerular mesangial cells, and collecting duct. COX-2 expression is restricted to the vasculature, cortical thick ascending limb (specifically in cells associated with the macula densa), and medullary interstitial cells. COX-2 expression in the macula densa increases in high-renin states (e.g., salt restriction, angiotensin-converting enzyme inhibition, and renovascular hypertension), and selective COX-2 inhibitors significantly decrease plasma renin levels and renal renin activity. COX-2 expression in the macula densa is reduced by angiotensin II and mineralocorticoids. Dehydration or hypertonicity appears to regulate COX-2 expression in the medullary interstitium. COX-2 is also necessary for normal renal development.

### Sodium Excretion

PGs are known to regulate renal sodium resorption by their ability to inhibit active transport of sodium in both the thick ascending limb and the collecting duct and to increase renal water excretion by blunting the actions of vasopressin.[93] The cellular source of COX-2–derived prostanoids that promote natriuresis remains uncertain, but it is possible that they may in large part be derived from the medullary interstitial cells. Sodium retention has been reported to occur in up to 25% of patients treated with NSAIDs and may be particularly apparent in patients who have an existing avidity for sodium, such as those with mild heart failure or liver disease.[93] Decreased sodium excretion in patients treated with NSAIDs can lead to weight gain and peripheral edema. This effect may be sufficiently important to cause clinically important exacerbations of congestive heart failure.

### Hypertension

NSAIDs may cause altered blood pressure, with average increases of mean arterial pressure of between 5 and 10 mm Hg. In addition, use of NSAIDs may increase the risk of initiating anti-hypertensive therapy in older patients, with the magnitude of increased risk being proportional to the NSAID dose.[94] Furthermore, in a large ($n$ = 51,630) prospective cohort of women aged 44 to 69 years without hypertension in 1990, incident hypertension during the following 8 years was significantly more likely in frequent users of aspirin, acetaminophen, and NSAIDs.[95] NSAIDs can attenuate the effects of anti-hypertensive agents, including diuretics, angiotensin-converting enzyme inhibitors, and β-blockers, thus interfering with control of blood pressure.

PGs stimulate renin release, which, in turn, increases secretion of aldosterone and, subsequently, potassium secretion by the distal nephron. For this reason, hyporeninemic hypoaldosteronism that manifests as type IV renal tubular acidosis and hyperkalemia may develop in patients treated with NSAIDs.[93] The degree of hyperkalemia is generally mild; however, patients with renal insufficiency or those who may otherwise be prone to hyperkalemia (e.g., patients with diabetes mellitus and those taking angiotensin-converting enzyme inhibitors or potassium-sparing diuretics) may be at greater risk.

### Acute Renal Failure and Papillary Necrosis

Acute renal failure is an uncommon consequence of NSAID treatment. Acute renal failure occurs because of the vasoconstrictive effects of NSAIDs, and it is reversible. In most cases, renal failure occurs in patients who have a depleted actual or effective intravascular volume (e.g., congestive heart failure, cirrhosis, or renal insufficiency).[93]

A marked reduction in medullary blood flow may result in papillary necrosis that may arise from apoptosis of medullary interstitial cells. Inhibition of COX-2 may be a predisposing factor.[92,96]

### Interstitial Nephritis

Another adverse renal effect resulting from NSAIDs involves an idiosyncratic reaction accompanied by massive proteinuria and acute interstitial nephritis. Hypersensitivity phenomena such as fever, rash, and eosinophilia may occur. This syndrome has been observed with most NSAIDs.

### Chronic Kidney Disease

Use of analgesics, particularly acetaminophen and aspirin, has been associated with nephropathy that leads to chronic renal failure. In one large case-control study, the regular use of aspirin or acetaminophen was associated with a risk of chronic renal failure 2.5 times as high as that for nonuse, and the risk increased significantly with an increasing cumulative lifetime dose.[97] In subjects regularly using both acetaminophen and aspirin, the risk was also significantly increased compared with users of either agent alone. No association between the use of nonaspirin NSAIDs and chronic renal failure could be detected after adjusting for acetaminophen and aspirin use. Pre-existing renal or systemic disease was a necessary precursor to analgesic-associated renal failure, and persons without pre-existing renal disease had only a small risk of end-stage renal disease.[97,98]

## Cardiovascular Effects

The risk of adverse cardiovascular effects associated with NSAID use was not widely appreciated until COX-2–selective NSAIDs were introduced into clinical practice.

Rofecoxib, a potent, highly specific COX-2 inhibitor with a long half-life, has a substantially increased risk of MI and stroke and was removed from the market because of this adverse effect.[7,69] The mechanisms for cardiovascular risks associated with all NSAIDs are likely related to an imbalance between complete inhibition of COX-1 and COX-2 across the dosing interval. The COX-1 isoform is responsible for the generation of platelet thromboxane $A_2$, which facilitates platelet aggregation and thrombus formation. To inhibit this activity, COX-1 must be inhibited by 95% or greater.[99] Anti-thrombotic $PGI_2$ synthesized by endothelial COX-2 is inhibited almost completely by both traditional and COX-2–selective NSAIDs. It is proposed that the relationship between excess cardiovascular risk for all NSAIDs, not only COX-2–selective NSAIDs, is related to the degree of COX-2 inhibition absent complete inhibition of COX-1.[100] Investigators have shown that drugs that inhibit COX-2 less than 90% at therapeutic concentrations in the whole blood assay present a relative risk for MI of 1.18 (95% CI, 1.02 to 1.38), whereas drugs that inhibit COX-2 to a greater degree present a relative risk of 1.60 (95% CI, 1.41 to 1.81).[100]

Relative inhibition of the COX isoforms is not the only mechanism that contributes to cardiovascular hazard. Other actions of NSAIDs, including effects on blood pressure, endothelial function, and NO production, as well as other renal effects, may play a role in cardiovascular risks.[69,101,102] Multiple analyses have demonstrated that the risk for cardiovascular hazard is significantly higher in persons with pre-existing coronary artery disease. Some NSAIDs, notably ibuprofen and naproxen, may interfere with the irreversible inhibition of platelet COX-1 by aspirin, thereby increasing the cardiovascular hazard in aspirin users.[100]

A number of large-scale randomized controlled trials comparing NSAIDs with placebo or with each other have been performed and analyzed to determine the risk of MI, stroke, cardiovascular death, death from any cause, and Anti-platelet Trialists' Collaboration (APTC) composite outcomes.[69] Because event rates in most of these studies were low, uncertainty regarding absolute and relative risk remains. A large network meta-analysis of 31 trials with 116,429 patients and more than 115,000 patient-years of follow-up was reported. The authors concluded that there is little evidence that any NSAID is safe in cardiovascular terms, although naproxen was potentially the least harmful.[103] It appears from analyses of these aggregated clinical trials that all traditional and COX-2–selective NSAIDs except naproxen carry an excess risk of more than 30% compared with placebo.[69] Pairwise comparisons of the most commonly used traditional and COX-2–selective NSAIDs studied in clinical trials also suggest that naproxen may have lower cardiovascular risk.[69] Estimation of absolute risk was performed in another comprehensive meta-analysis of clinical trials.[104] Compared with placebo, allocation to a COX-2–selective NSAID (with celecoxib grouped together with rofecoxib and others) or diclofenac caused approximately three additional major vascular events per 1000 participants per year. One meta-analysis explored the effects of dose and dosing regimen in a pooled analysis of six randomized placebo-controlled trials of celecoxib.[105] Lower doses and once-daily regimens were associated with lower relative risks for the APTC outcomes. This finding confirms data from other studies that suggest that avoiding continuous interference with PG biosynthesis is associated with lower cardiovascular risk.[100]

Because clinical trials have been underpowered to specifically address the relative cardiovascular risk of NSAIDs, investigators have turned to observational data sets. Using a large observational database with 8852 cases of nonfatal MI, a recent case-control study also identified a 35% increase in the risk of MI while using NSAIDs.[100] In a nationwide cohort of patients after MI, an increased risk of death or recurrent MI of approximately 50% for patients using NSAIDs was present at the beginning of treatment and persisted throughout the observation period.[106] The largest meta-analysis of observational studies available to date also clearly demonstrates that higher doses of NSAIDs, with the exception of naproxen, increased the risk of serious cardiovascular events.[107] The effect of dose and slow-release formulation demonstrated that risk was a direct consequence of prolonged drug exposure. It appears that the risk associated with these pharmacologic factors may be even more important than COX-2 specificity for most NSAIDs.[69,100]

A number of strategies have been suggested to mitigate cardiovascular risks associated with NSAID use (Table 59-4).[108] These recommendations take into account a patient's underlying risk, aspirin use, and the interaction between NSAIDs. In addition, the specific choice of NSAID should consider its pharmacologic properties.[69,100]

### Heart Failure

NSAIDs are associated with reduced sodium excretion, volume expansion, increased preload, and hypertension. As a result of these properties, patients with pre-existing heart failure are at risk of decompensation with a relative risk of 3.8 (95% CI, 1.1 to 12.7). After adjusting for age, sex, and concomitant medication, the relative risk was 9.9 (95% CI, 1.7 to 57.0).[109] Studies disagree as to whether NSAIDs are a risk for new episodes of heart failure, although elderly persons may be at particular risk.[109,110] A recent study examining patients who survived first hospitalization for heart failure demonstrated increased risk of death with all NSAIDs at high doses and again demonstrated that lower doses reduced risk for all agents.[111]

### Closure of the Ductus Arteriosus

The maintenance of an open ductus arteriosus and its closure during the postnatal period are regulated by PG.

**TABLE 59-4** Strategies for Reducing Cardiovascular Risk[69,100,108]

| |
|---|
| If using aspirin, take aspirin dose ≥2 hr before NSAID dose.* |
| Do not use NSAIDs within 3-6 mo of an acute cardiovascular event or procedure. |
| Carefully monitor and control blood pressure. |
| Use low-dose, short–half-life NSAIDs and avoid extended-release formulations. |

*Especially ibuprofen. Celecoxib does not appear to interfere with aspirin actions.

COX-1, COX-2, and $EP_4$-deficient mice die from neonatal circulatory failure because the ductus arteriosus remains open. It is inadvisable for pregnant women to take NSAIDs during the last trimester of pregnancy because of the risk of a persistently patent ductus arteriosus.

## Hepatic Effects

Small elevations of one or more liver tests may occur in up to 15% of patients taking NSAIDs, and notable elevations of alanine aminotransferase or aspartate aminotransferase (approximately three or more times the upper limit of normal) have been reported in approximately 1% of patients in clinical trials of NSAIDs. Patients usually have no symptoms, and discontinuation or dose reduction generally results in normalization of the transaminase values, although rare, fatal outcomes have been reported with almost all NSAIDs. The NSAIDs that appear most likely to be associated with hepatic adverse events are diclofenac and sulindac.

In clinical trial reports to the FDA, 5.4% of patients with RA who were treated with aspirin experienced persistent elevations of results in more than one liver function test. In children with viral illnesses, hepatocellular failure and fatty degeneration (Reye's syndrome) are associated with aspirin ingestion.[58]

## Asthma and Allergic Reactions

### Asthma

Up to 10% to 20% of the general asthmatic population, especially those with the triad of vasomotor rhinitis, nasal polyposis, and asthma, are hypersensitive to aspirin. In these patients, ingestion of aspirin and nonspecific NSAIDs leads to severe exacerbations of asthma with naso-ocular reactions. These patients, who were formerly said to have aspirin-sensitive asthma, are now characterized as having aspirin-exacerbated respiratory disease (AERD) because they have chronic upper and lower respiratory mucosal inflammation, sinusitis, nasal polyposis, and asthma independent of their hypersensitivity reactions. It is now thought that production of protective PGs in the setting of AERD is derived from a COX-1. A number of studies have been reported demonstrating that the COX-2–specific NSAIDs, rofecoxib and celecoxib, fail to trigger asthma exacerbation or naso-ocular symptoms in patients with AERD.[112,113] Nevertheless, these studies were performed as challenge tests rather than long-term placebo-controlled trials, and caution is advised. The fact that specific COX-2 inhibitors appear safe in persons with AERD does not imply that other hypersensitivity reactions do not occur.

### Allergic Reactions

A wide variety of cutaneous reactions have been associated with NSAIDs. Almost all the NSAIDs have been associated with cutaneous vasculitis, erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. NSAIDs are also associated with urticaria/angioedema and anaphylactoid or anaphylactic reactions. It should be especially noted that celecoxib and valdecoxib contain a sulfonamide group and should not be given to patients who report allergy to drugs containing sulfa.

## Hematologic Effects

Aplastic anemia, agranulocytosis, and thrombocytopenia are rarely associated with NSAIDs, but they are prominent among the causes of deaths attributed to these drugs. Because of the risk of hematologic effects, phenylbutazone is no longer recommended for use in any condition in the United States and has been taken off the market.[114]

## Effects on the Immune System

Virtually all cell types comprising the immune system produce and respond to PGs. $PGE_2$ is a potent inhibitor of chemotaxis, aggregation, superoxide production, lysosomal enzyme release, and $LTB_4$ generation of activated neutrophils.[115] Antigen-presenting cells play a pivotal role in the immune response, bridging local innate immune responses and the developing acquired immune response, which takes place in more specialized lymphoid organs. Bone marrow cultured in the presence of indomethacin yields increased numbers of dendritic cells, whereas bone marrow cultured in the presence of exogenous $PGE_2$ yields lower numbers of dendritic cells.[116] Dendritic cell cytokines are one of the many important factors that polarize the T cell response toward T helper (Th)1, Th2, or Th17 cytokine profiles. Failure of dendritic cell maturation and/or their secretion of inhibitory cytokines leads to development of T regulatory cells that modulate Th activity and suppress some of their functions.[117] Eicosanoids are likely to be one of the tissue factors that determine dendritic cell phenotype during interaction with specific antigens/pathogens via pattern recognition receptors.[117] Exogenous $PGE_2$ was reported to induce IL-23 production, which is important for generation of Th17 cells.[118,119] A recent study using human peripheral blood mononuclear cells also supports a role for $PGE_2$ in promoting a Th17 response.[120] Although a Th17 immune response is associated with development of autoimmune diseases, the clinical relevance of these observations with respect to NSAID use remains unclear.

$PGE_2$ also plays a role in B and T lymphocytes. $PGE_2$, through increased cAMP, inhibits many T cell functions.[121] Treatment with COX-2–selective NSAIDs severely diminishes proliferation and expression of IL-2, TNF, and IFN-γ. B lymphocytes express COX-2 and produce $PGE_2$.[122] Treatment with traditional and COX-2–selective NSAIDs profoundly reduced production of IgG and IgM after stimulation with minimal effects on proliferation. COX-2 null mice had 64% less IgM and 35% less IgG than normal littermates after in vitro treatment with LPS. COX-2–deficient mice also produce markedly reduced IgG and 10-fold reduced neutralizing antibody to HPV-like particles compared with wild-type mice without evidence of differences in B cell precursors.[123] Similar findings of deficient humoral immune responses have been demonstrated for mice deficient in mPGES-1.[124] Human memory B cell antibody production was also diminished in the presence of a specific COX-2 inhibitor.[123] Again, the clinical relevance of these observations remains unclear with respect to NSAID use.

## CNS Effects

Elderly patients may be particularly susceptible to developing cognitive dysfunction and other CNS effects, including headache, dizziness, depression, hallucination, and seizures, that are related to NSAIDs. Acute aseptic meningitis has been reported in patients with SLE or mixed connective tissue disease who were treated with ibuprofen, sulindac, tolmetin, or naproxen.

## Effects on Bone

The complex effects of prostanoids on bone formation and remodeling have been appreciated for many years. It is now clear that COX-2 is required for many functions of both osteoblasts and osteoclasts.[27] COX-2 is rapidly inducible and highly expressed and regulated in osteoblasts. Parathyroid hormone (PTH) is a strong inducer of COX-2. The production of PG by osteoblasts is an important mechanism for the regulation of bone turnover.[27] The major effect of $PGE_2$ is considered to occur indirectly via upregulation of receptor activator of NF-κB ligand (RANKL) expression and by inhibition of osteoprotegerin (OPG) expression in osteoblastic cells, which facilitates osteoclastogenesis. Genetic deletion of *PTGS2* or COX-2–selective NSAIDs partially block the PTH- or 1,25-OH vitamin D–induced formation of osteoclasts in organ cultures. Recently, a familial disorder, primary idiopathic hypertrophic osteoarthropathy, was found to be associated with a mutation in the enzyme 15-hydroxyprostaglandin dehydrogenase, the enzyme that inactivates $PGE_2$.[125] These patients have chronically elevated $PGE_2$ levels and digital clubbing with evidence of increased bone formation and resorption in the phalanges.

The role of endogenous PG and NSAIDs in skeletal disease remains complex. LPS-induced bone loss can be ameliorated in mice lacking mPGES-1.[126] Inflammatory bone loss likely reflects increased bone resorption and decreased bone formation.[27] It has long been appreciated that NSAIDs can inhibit experimental fracture healing and reduce formation of heterotopic bone in patients.[127] Furthermore, fracture healing is impaired in rats treated with specific COX-2 inhibitors and in mice with genetic deletion of the *COX-2* gene *(PTGS2)*.[128] Given the effectiveness of NSAIDs as analgesics, it is important to understand the clinical concern regarding impaired fracture healing and NSAIDs. A recent meta-analysis found a pooled odds ratio of 3 for nonunion with NSAID exposure (95% CI, 1.6 to 5.6).[129] However, there was a significant association between lower-quality studies, and higher-reported odds ratios for nonunion were observed. When only higher-quality studies were considered, no statistically significant association between NSAID exposure and nonunion was identified.

The impact of NSAIDs on bone mineral density (BMD) also remains unclear.[27] In older men, daily use of COX-2–selective NSAIDs was associated with lower hip and spine BMD compared with nonusers, but in post-menopausal women not taking hormone replacement therapy, a higher BMD was found.[130] It is speculated that the beneficial effects of mechanical loading may be reduced by COX-2 inhibition but that the pro-inflammatory state and increased bone turnover associated with estrogen withdrawal may be suppressed by COX-2 inhibition. Still, a causal role for endogenous PGs in bone loss resulting from estrogen deficiency has not been confirmed.

## Effects on Ovarian and Uterine Function

PGs derived from COX-2 have been implicated as mediators in multiple stages of the female reproductive cycle. Induction of COX-2 immediately after the luteinizing hormone surge was the first observation involving the isoenzyme during a normal physiologic event. It has been suggested that COX-2–derived PGs may signal the time of ovulation in mammals.[131,132] Studies using COX-2 null mice show reproductive failure at ovulation, fertilization, implantation, and decidualization.[133] COX-2–dependent prostanoid production probably leads to the generation of proteolytic enzymes that rupture the follicles. After fertilization, COX-2 also plays a role in embryo implantation in the myometrium.[133] PGs are important for inducing uterine contractions during labor. Murine studies have shown that the mechanism of uterine contraction involves fetal release of $PGF_{2\alpha}$, a compound that induces luteolysis. This pathway leads to reduced maternal progesterone levels, induction of oxytocin receptors in the myometrium, and parturition.

Based on these observations in animals, one could hypothesize that NSAIDs may have an influence on fertility. In fact, studies suggest that luteinized unruptured follicle syndrome as a cause of reversible infertility can be related to the ingestion of NSAIDs.[134] For this reason, although it remains unproved in controlled or observational studies, women should be cautioned that chronic NSAID use may impair fertility.

## Salicylate Intoxication and NSAID Overdose

The new appearance of tachypnea, confusion, ataxia, oliguria, or a rising blood urea nitrogen/creatinine level in a patient, particularly an elderly patient, who takes aspirin or salicylates should suggest the possibility of salicylate intoxication. In adults, metabolic acidosis is masked by hyperventilation because of the stimulation of respiratory centers, which is a direct effect of salicylates. Sudden increases in salicylate levels can occur even if there is no change in dose. This increase is particularly common in patients who experience acidosis from any cause, experience dehydration, or ingest other drugs that displace salicylate from protein-binding sites. Therapy consists of removing residual drug from the GI tract, forced diuresis while maintaining the urinary pH in the alkaline range and with potassium replacement, or hemodialysis if diuresis is unsatisfactory. Vitamin K is recommended because large doses of salicylate may interfere with the synthesis of the vitamin K–dependent clotting factors.

Acute overdoses of NSAIDs are much less toxic than are overdoses of aspirin or salicylates. This subject has been most carefully evaluated for ibuprofen, prompted by its approval for over-the-counter sale to the general public. Symptoms with overdoses ranging up to 40 g include CNS depression, seizures, apnea, nystagmus, blurred vision, diplopia, headache, tinnitus, bradycardia, hypotension, abdominal pain, nausea, vomiting, hematuria, abnormal

renal function, coma, and cardiac arrest. Treatment includes prompt evacuation of the stomach contents, observation, and administration of fluids.

### Adverse Effects of Acetaminophen

Acetaminophen is used widely as the first-line treatment of pain, chiefly because it is viewed as effective and safer than NSAIDs. When used in doses of less than 2 g daily, there is little evidence of toxicity.[135] Acetaminophen-induced acute liver failure is a result of direct injury from the toxic metabolite, *N*-acetyl-*p*-benzoquinoneimine, a highly reactive electrophilic compound that depletes glutathione and subsequently accumulates in hepatocytes.[136] Acetaminophen is a highly predictable hepatotoxin with a threshold dose of 10 to 15 g in adults and 150 mg/kg in children (lower dosages have also been associated with hepatic injury). In the United States, acetaminophen overdoses are usually unintentional, with most persons taking acetaminophen preparations for chronic pain. Intentional self-poisoning with acetaminophen also remains an important problem. Treatment of acetaminophen overdose includes gastric lavage, activated charcoal, or induction of vomiting within the first 3 hours of injection. In addition, intensive support measures and early treatment with *N*-acetylcysteine, which replenishes glutathione, have reduced the mortality associated with acute acetaminophen toxicity. With high doses of acetaminophen, other toxicities may occur, including GI ulcers and bleeding.[137,138] Regular use of acetaminophen has also been associated with an increased risk for chronic renal failure.[97]

## EFFECTS OF CONCOMITANT DRUGS, DISEASES, AND AGING

Because of the widespread use of prescription and nonprescription NSAIDs, ample opportunities exist for interaction with other drugs and for interactions with patient-specific factors.[139] Specific drug interactions are listed on the package inserts of individual agents.

### Drug-Drug Interactions

Because most NSAIDs are extensively bound to plasma proteins, they may displace other drugs from binding sites or may themselves be displaced by other agents. Aspirin and other NSAIDs may increase the activity or toxicity of sulfonylurea, hypoglycemic agents, oral anti-coagulants, phenytoin, sulfonamides, and methotrexate by displacing these drugs from their protein-binding sites and increasing the free fraction of the drug in plasma.[139] NSAIDs may blunt the anti-hypertensive effects of β-blockers, angiotensin-converting enzyme inhibitors, and thiazides, leading to destabilization of blood pressure control.[140] An increased risk of GI toxicity is present when NSAIDs and selective serotonin reuptake inhibitors are taken concomitantly compared with taking either agent alone, and more than an additive risk occurs.[141]

Interactions between aspirin and NSAIDs, particularly ibuprofen, are related to blocking of the ability of aspirin to access the COX active site. This effect may be important when aspirin is used for the prevention of cardiovascular disease. It is prudent to recommend that aspirin be taken 2 hours before ingestion of ibuprofen.[108,142]

### Drug-Disease Interactions

RA and other diseases (e.g., hepatic and renal disease) that decrease serum albumin concentrations are associated with increased concentrations of free NSAIDs. Hepatic and renal diseases also may impair drug metabolism or excretion and thereby increase the toxicity of a given dose of an NSAID to an individual patient. Renal insufficiency may be accompanied by accumulated endogenous organic acids that may displace NSAIDs from protein-binding sites.

### Drug Reactions in Elderly Persons

Aging is accompanied by changes in physiology, resulting in altered pharmacokinetics and pharmacodynamics. Decreased drug clearance may be the consequence of reductions in hepatic mass, enzymatic activity, blood flow, renal plasma flow, glomerular filtration rate, and tubular function associated with aging. Elderly persons are more likely to experience adverse GI and renal effects related to NSAIDs. The increased risk of cardiovascular disease in elderly patients raises concerns of accelerated MI or stroke. The use of aspirin for prevention of cardiovascular disease increases the toxicity of NSAIDs, and conversely the concomitant use of NSAIDs may increase aspirin resistance. Use of a PPI for gastroprotection may interfere with the efficacy of antiplatelet agents such as clopidogrel.[142] Elderly persons have more illnesses than younger patients and therefore take more medications, increasing the possibility of drug-drug interactions. Older patients also may be more likely to self-medicate or make errors in drug dosing. For these reasons, frequent monitoring for compliance and toxicity should accompany the use of NSAIDs in this population.

### Colchicine

Colchicine is frequently used in the context of NSAID replacement therapy when NSAIDs are contraindicated. Colchicine exhibits excellent anti-inflammatory activity in acute gouty arthritis. A recent study has clarified that a low-dose colchicine regimen of 1.2 mg followed in 1 hour by 0.6 mg provides equal efficacy to higher-dose regimens, with a marked reduction in adverse events.[143] Colchicine is also used to prevent acute gouty attacks. Prophylactic treatment appears to reduce the frequency of attacks by 75% to 85% and mitigates the severity of attacks that occur.[144] However, there is concern that prophylactic therapy should be initiated only if hyperuricemia is controlled because tophi may develop without the usual warning signs of acute gouty attacks. Albeit with less efficacy, colchicine treatment also may benefit patients with acute episodes of pseudogout and arthritis resulting from other crystals.

Daily use of colchicine (1.2 to 1.8 mg) is the mainstay of treatment for familial Mediterranean fever (FMF). It is effective in preventing acute attacks and amyloidosis. Colchicine has been used empirically in other rheumatologic disorders in which neutrophils play an important role, such as Behçet's disease, recurring pericarditis, and cutaneous neutrophilic vasculitis.[145]

### Mechanism of Colchicine Action

Colchicine appears to interfere with steps of the inflammatory response in which neutrophils play a central role by interfering with the organization of the fibrillar microtubules involved in cell structure and movement. This interference leads to disaggregation of microtubules and to decreased neutrophil motility and chemotaxis. Furthermore, colchicine inhibits release of chemotactic factors (e.g., leukotriene $B_4$), formation of digestive vacuoles, and lysosomal degranulation, resulting in an inhibition of neutrophil migration into an area of inflammation and a reduction of the metabolic and phagocytic activity of the neutrophils already present. Clinically, this effect results in an interruption in the inflammatory process of gout and other neutrophil-dominated acute inflammatory diseases.[143]

### Adverse Effects of Colchicine

Because the mechanism of colchicine actions is different from that of NSAIDs, the adverse event profile is also different. More than 80% of patients who take a traditional high-dose oral therapeutic dose of colchicine for an acute gouty attack experience cramping, abdominal pain, diarrhea, nausea, or vomiting, and these symptoms usually limit the dose. For this reason, and because of equal efficacy, high-dose colchicine is not recommended for acute gout flares.[143]

Bone marrow depression, hair loss, amenorrhea, dysmenorrhea, oligospermia, and azoospermia have been reported with chronic colchicine treatment.[138] An increase in trisomy 21 may occur in the offspring of patients with FMF who take colchicine at the time of conception. Colchicine can cause subacute-onset muscle and peripheral nerve toxicity, particularly in patients with chronic renal failure. For this reason, colchicine should be used cautiously in patients with chronic renal failure, and dose adjustment should be considered. Patients with colchicine-induced neuromyopathy present with proximal muscle weakness, elevated serum creatine kinase levels, and neuropathy and/or myopathy on electromyography.[146]

Death has occurred with as little as 8 mg of colchicine but is inevitable after the ingestion of more than 40 mg. Treatment includes aspiration of the stomach, intensive support measures, and hemodialysis, although no specific evidence exists that colchicine can be removed by dialysis.

## CHOOSING ANTI-INFLAMMATORY ANALGESIC THERAPY

In choosing an NSAID for a particular patient, the clinician must consider efficacy, potential toxicity related to concomitant drugs and patient factors, and cost. Furthermore, patient preference for factors such as dosing regimen may be taken into account. In addition to choices from the perspective of the individual patient and physician, it may be important to take a broader view. Choice of anti-inflammatory analgesic therapy can also be considered from the perspective of health care institutions and payers. The symptoms and conditions for which NSAIDs are used are extraordinarily common. Consequently, the cost of NSAIDs as a proportion of total drug costs can be high when drugs are expensive. The increased cost of branded NSAIDs has an important pharmacoeconomic impact. On the other hand, adverse events can have important economic consequences, and improved safety may be cost-effective.

Choosing anti-inflammatory analgesic therapy has become increasingly complex with the increased understanding of associated toxicities. Prospectively considering the presence of GI and cardiovascular risk factors is essential when considering treatment options (Table 59-5). GI risks

**TABLE 59-5** Choosing Anti-inflammatory Analgesic Therapy

| Risk Category | Treatment Recommendations |
|---|---|
| **Low** | |
| <65 yr<br>No cardiovascular risk factors<br>No requirement for high-dose or chronic therapy<br>No concomitant aspirin, corticosteroids, or anti-coagulants | Traditional NSAID<br>Shortest duration and lowest dose possible |
| **Intermediate** | |
| ≥65 yr<br>No history of previous complicated GI ulceration<br>Low cardiovascular risk, may be using aspirin for primary prevention<br>Requirement for chronic therapy and/or high-dose therapy | Traditional NSAID + PPI, misoprostol, or high-dose H2RA<br>Once-daily celecoxib + PPI, misoprostol, or high-dose H2RA if taking aspirin<br>If using aspirin, take a low dose (75-81 mg)<br>If using aspirin, take a traditional NSAID ≥2 hr before aspirin dose |
| **High** | |
| Elderly, especially if frail or if hypertension, renal disease, or liver disease is present<br>History of previous complicated ulcer or multiple GI risk factors<br>History of cardiovascular disease and taking aspirin or another anti-platelet agent for secondary prevention<br>History of heart failure | Use acetaminophen, <2 g/day<br>Avoid chronic use of NSAIDs if at all possible:<br>Use intermittent NSAID dosing<br>Use low-dose, short–half-life NSAIDs<br>Do not use an extended-release NSAID formulation<br>If chronic NSAID use is required, consider:<br>Once-daily celecoxib + PPI/misoprostol (GI > CV risk)<br>Naproxen + PPI/misoprostol (CV > GI risk)<br>Avoid use of a PPI if using an anti-platelet agent such as clopidogrel<br>Monitor and treat blood pressure<br>Monitor creatinine and electrolytes |

CV, Cardiovascular; GI, gastrointestinal; H2RA, histamine-2-receptor antagonist; PPI, proton pump inhibitor.

are well known, and strategies to prevent ulceration and bleeding are available. Many questions regarding the risk for cardiovascular events in patients using NSAIDs exist. In general, the data suggest that physicians should be cautious in using NSAIDs in patients with known cardiovascular disease. In patients with risks for NSAID toxicity, avoiding potent drugs with a long half-life or extended-release formulations is prudent. Intermittent dosing rather than continuous daily use reduces toxicity.

Absence of anti-inflammatory activity reduces the effectiveness of acetaminophen for diseases accompanied by a significant component of inflammation (e.g., RA and gout). However, acetaminophen is a safe and effective alternative for milder pain conditions, including osteoarthritis. With respect to patient preference, a survey study demonstrated that only 14% of a large group of patients with rheumatic disease ($n = 1799$) who had RA, osteoarthritis, or fibromyalgia preferred acetaminophen rather than NSAIDs, whereas 60% preferred NSAIDs.[147] In a head-to-head clinical trial of acetaminophen versus diclofenac plus misoprostol, patients in the diclofenac group had significantly greater improvement in pain scores. This finding was magnified in patients with more severe disease at baseline.[148]

Acetaminophen can be tried as the initial therapy in patients with mild to moderate pain for reasons of safety and cost. However, a recent meta-analysis of the safety and efficacy of acetaminophen for spinal pain and osteoarthritis found that this agent is ineffective in the treatment of low back pain and provides minimal short-term benefit for people with osteoarthritis.[149] Furthermore, patients taking acetaminophen were nearly four times more likely to have abnormal results on liver function tests. If patients have moderate to severe symptoms or if evidence of inflammation is present, moving to treatment with NSAIDs may provide more rapid and effective relief.[150]

## CONCLUSION

The strategy of blocking PG production by inhibiting the COX enzymes has provided relief from pain and inflammation for centuries. Given the proven importance of PG in this pathway and the advances in understanding the molecules involved, pharmacologic targeting of enzymes involved in biosynthesis, transport, or degradation may provide therapeutic efficacy. Similar to COX-2, mPGES-1 is induced during inflammation and in other pathologic states. Strategies to inhibit mPGES-1 have been proposed as potential alternatives to inhibiting COX.[151] Drug development has been somewhat hampered because of the species specificity of mPGES-1 binding. However, this strategy may be particularly appealing because pre-clinical data suggest that inhibition of mPGES-1 is associated with a reduced propensity to develop hypertension, thrombosis, atherosclerotic plaques, aortic aneurysm, and neointimal hyperplasia after vascular injury.[152-154] Additionally, receptor antagonists also could be useful. Indeed, a number of $EP_4$ receptor antagonists have proved useful in animal models of RA, osteoarthritis, and pain.[18]

CHAPTER 60

# Glucocorticoid Therapy

Johannes W.G. Jacobs • Johannes W.J. Bijlsma

**KEY POINTS**

- The mode of action of glucocorticoids is due to interactions between the glucocorticoid receptor and genomic DNA and, in high dosages, might operate through non-genomic mechanisms.
- Glucocorticoids differ considerably in potency and biologic half-life.
- Cortisone and prednisone are biologically inactive and are converted in the liver into biologically active cortisol and prednisolone, respectively.
- Glucocorticoids have disease-modifying and joint-sparing properties in the early phase of rheumatoid arthritis.
